The heart consists of four chambers: two large ventricles with thick muscular walls making up the bulk of the organ, and two smaller atria with thin muscular walls. The atria are directed toward the **base** of the heart, while the ventricles are oriented toward the **apex**. The septum that separates the ventricles also extends between the atria, subdividing the whole heart into what frequently are called **left and right halves or sides** of the heart. As they lie in the body, however, the right side is mostly ventral or anterior and the left side largely dorsal or posterior.

**SURFACE SULCI.** The atria are separated from the ventricles on the surface of the heart by the **coronary sulcus** (Figs. 7-25; 7-26). This groove encircles the heart and is occu-

pied by the coronary vessels that supply the heart. The sulcus is deficient anteriorly because the root of the pulmonary trunk arises from the right ventricle at this site. The **interatrial groove**, which separates the two atria, is scarcely marked on the posterior surface, while anteriorly it is hidden by the pulmonary trunk and the aorta. The line of separation between the two ventricles is marked by the **anterior interventricular sulcus** on the sternocostal surface and by the **posterior interventricular sulcus** on the diaphragmatic surface. Within these two sulci course the anterior and posterior interventricular branches of the coronary arteries and their accompanying veins (Figs. 7-25; 7-26). The two grooves become continuous just to the right of the apex at a notch termed the **apical incisure** of the heart.

**THE APEX.** The **apex** of the heart points forward, to the left, and downward. Although its position changes continually during life, the tip remains close to the following point under usual circumstances: deep to the left fifth intercostal space, 8 or 9 cm from the midsternal line. This is about 4 cm below and 2 cm medial to the left nipple in the male. Because the site of the nipple can vary somewhat in females, this latter means of approximating the position of the apex may be less useful. The apex is overlapped by an extension of the pleura and lungs as well as by the structures of the anterior thoracic wall.

**THE BASE.** Although the base of the heart is somewhat more difficult to visualize than the apex, it can be conceived as the base of a blunt cone oriented in a direction opposite the apex. It faces backward, to the right, and upward. It is nearly quadrilateral in shape and is formed mainly by the left atrium, part of the right atrium, and the proximal parts of the great vessels (Fig. 7-27). The base of the heart extends superiorly as far as the bifurcation of the pulmonary trunk, while inferiorly it is bounded by the posterior part of the coronary sulcus containing the coronary sinus. To the **right** it is limited by the sulcus terminalis of the right atrium and to the **left** by the oblique vein of the left atrium. The descending thoracic aorta, the esophagus, and the thoracic duct intervene between the base of the heart and the bodies of the fifth to eighth thoracic vertebrae. At the base of the heart, the four pulmonary veins, two on

**FIG. 7-24.** The anterior or sternocostal surface of the heart and great vessels after removal of the anterior part of the pericardium.

each side, open into the left atrium, while the superior vena cava opens into the upper part and the inferior vena cava into the lower part of the right atrium.

**SURFACES AND MARGINS.** The heart presents several surfaces and margins (or borders) which upon clinical examination can be useful in describing surface relationships and possible pathological distortion of its normal shape and contours.

The **sternocostal surface** is formed by the right atrium, and especially its auricular appendage, and the right ventricle, to the left of which is a small part of the left ventricle (Fig. 7-25). The right upper aspect of this surface is crossed obliquely by the coronary sulcus, while the anterior interventricular sulcus passes from above downward and forms a line of separation between the right and left ventricles.

The **diaphragmatic surface** is formed prin-

cipally by the left ventricle, but also to some extent by the right ventricle (Fig. 7-26). It rests chiefly upon the central tendon of the diaphragm, and it is crossed obliquely by the posterior interventricular sulcus. Superiorly, it is separated from the base of the heart by the coronary sulcus.

**Right Margin.** The right margin of the heart is longer than the left, and it describes an arc from the superior vena cava to the apex. Its upper part defines the margin of the right atrium, while the lower part of the right margin outlines the border of the right ventricle. Because the right ventricle lies nearly horizontally on the diaphragm, so does the lower part of the right margin. Coursing along the line of attachment of the diaphragm to the anterior chest wall, the ventricular part of the right margin tends to be thin and sharp. It extends from the sternal end of the sixth right costal cartilage to the

FIG. 7-25. The sternocostal surface of the heart viewed from the anterior aspect. (Modified after Sobotta.)

cardiac apex and is sometimes called the **acute margin**, or even the **inferior border**, of the heart. The *atrial part* of the right margin is almost vertical and is situated behind the third, fourth, and fifth costal cartilages, 1.25 cm to the right of the margin of the sternum.

**Left Margin.** The left margin is shorter and more rounded, and is formed mainly by the left ventricle and to a small extent by the left atrium. It extends obliquely downward to the apex from a point 2.5 cm from the sternal margin in the second left interspace, describing a curve that is convex laterally to the left.

## Chambers of the Heart

The interior of the human heart consists of four chambers, two **atria** superiorly, and two **ventricles** inferiorly. A continuous septum, passing from the apex to the base, separates

the atria (**interatrial septum**) and the ventricles (**interventricular septum**). On each side of the heart the passage between the atrium and the ventricle is guarded by valves (**right and left atrioventricular valves**). Other valves (the **aortic valve** and the **pulmonary valve**) are interposed between the ventricles and the principal arteries leaving the heart. The interior of each of the four chambers presents specialized structures that contribute to its function.

### RIGHT ATRIUM

The right atrium (Fig. 7-28) is a somewhat cuboid chamber that has a capacity of about 57 ml. It appears larger than the left, and its wall, which is about 2 mm in thickness, is thinner than that of the left atrium. It consists of two parts: a principal cavity, situated posteriorly, called the **sinus venarum**, and a more anterior, smaller, conical pouch called the **right auricle** (Fig. 7-28).

**FIG. 7-26.** The diaphragmatic surface and the base of the heart viewed from the dorsal aspect. The visceral pericardium still overlies the heart, but observe the cut edges of its reflection as the parietal pericardium over the large vessels. (After Sobotta.)

**SINUS VENARUM.** The sinus venarum is the part of the right atrium located between the superior and inferior venae cavae and the atrioventricular opening (Fig. 7-28). Its wall merges with these two large veins, and its interior surface is quite smooth except for certain rudimentary structures to be described.

**RIGHT AURICLE.** The right auricle is a small, conical, muscular pouch which is an extension of the right atrium (Fig. 7-28). It is directed upward and to the left between the superior vena cava and the right ventricle, overlapping the right side of the root of the aorta. The junction of the right auricle with the sinus venarum is marked on the exterior of the atrium by a groove, the **sulcus terminalis** (Fig. 7-27), which corresponds to a ridge on the atrial inner surface, the **crista terminalis**. The internal surface of the auricle has its muscular bundles raised into

distinctive parallel ridges resembling the teeth of a comb and named, therefore, the **musculi pectinati**.

In addition to the **crista terminalis** and the **musculi pectinati**, the interior of the right atrium presents for examination a number of openings, valves, and other specialized structures.

**OPENING OF THE SUPERIOR VENA CAVA.** The superior vena cava opens into the upper posterior part of the sinus venarum (Fig. 7-28). Its orifice is oriented downward and forward so that blood entering the atrium through it is directed toward the atrioventricular opening. The superior vena cava returns blood from the cranial half of the body, and there is no valve at its opening in the right atrium.

**OPENING OF THE INFERIOR VENA CAVA.** The inferior vena cava opens into the most caudal part of the sinus venarum near the inter-

**FIG. 7-27.** The base of the heart viewed from the dorsal and superior aspect. Pulmonary artery shown in blue because of low blood oxygenation level; pulmonary veins shown in red because of high blood oxygenation level.

**FIG. 7-28.** Interior of the right atrium and right ventricle after the removal of the sternocostal wall of the heart. Pulmonary trunk and pulmonary arteries shown in blue to indicate the low level of oxygenation of the blood in these vessels.

atrial septum. Returning blood from the lower half of the body, its orifice is larger than that of the superior vena cava. This opening is directed upward and backward toward the fossa ovalis, and the rudimentary **valve of the inferior vena cava** extends a short distance superiorly from the opening on the interatrial septum.

**VALVE OF THE INFERIOR VENA CAVA.** This valve (sometimes called the Eustachian valve<sup>1</sup>) is a single crescentic fold attached along the anterior and left margin of the orifice of the inferior vena cava. Its concave free margin ends in two cornua, of which the left is continuous with the anterior margin of the limbus fossae ovalis and the right spreads out on the atrial wall. The valve consists of a fold of the membranous lining of the atrium containing a few muscular fibers. In the fetus the valve is more prominent and tends to direct blood from the inferior cava to the left atrium through the foramen ovale, which is open prenatally. In the adult the valve is usually rudimentary and has little if any functional significance. It may be thin and fenestrated, very small, or even entirely absent.

**OPENING OF THE CORONARY SINUS.** The coronary sinus opens into the right atrium between the orifice of the inferior vena cava and the atrioventricular opening. It returns most of the blood from the substance of the heart itself and the opening is protected by a thin valve.

**VALVE OF THE CORONARY SINUS.** This valve is a single semicircular fold of the lining membrane of the right atrium, and it is attached to the right and inferior lips of the orifice of the coronary sinus. It may have a cribriform structure and contain many perforations or it may be doubled. The valve is seldom effective for more than partial closure of the orifice during contraction of the atrium.

**FORAMINA VENARUM MINIMARUM.** These are openings of small veins, the *venae cordae minimi* (or thebesian veins), which drain blood from the heart muscle directly into the atrial cavity. A few larger orifices can usually be seen in the septal wall, including those of the anterior cardiac veins. These openings were used by early scientists

to explain the passage of blood from one side of the heart to the other before William Harvey<sup>2</sup> discovered the circulation of blood in 1610 A.D.

Another orifice in the right atrium is the right atrioventricular opening, a large oval aperture of communication between the atrium and the right ventricle. It is described with the right ventricle.

**INTERATRIAL SEPTUM.** The interatrial septum forms the dorsal wall of the right atrium. It contains rudimentary structures which were of significance in the fetus. The **fossa ovalis** (Fig. 7-28) is an oval depression in the lower part of the septal wall and corresponds to the foramen ovale of the fetal heart. It lies within a triangular area bounded by the openings of the two venae cavae and the coronary sinus. Its floor is formed by the remnant of the septum primum that initially separated the atria in the fetus.

The **limbus fossae ovalis** is the prominent oval margin of the foramen ovale and represents the free border of the septum secundum. The latter fetal structure forms just to the right of the septum primum in the fetus, and from it is derived most of the muscular part of the interatrial septum in the adult—that is, all except the floor of the fossa ovalis, which persists from the septum primum. The limbus is distinct cranially and at the sides, but it is deficient caudally. Frequently the cranial part of the two fetal septi do not fuse, leaving a slit-like opening in the adult interatrial septum through which a probe may be passed into the left atrium. This is spoken of as *probe patency* of the foramen and is found in 20 to 25% of all hearts. Larger openings are not uncommon, but these interatrial defects are seldom of functional significance.

The **intervenous tubercle** (of Lower<sup>3</sup>) is a small raised area in the septal wall of the right atrium between the fossa ovalis and the orifice of the superior vena cava. It is more distinct in the hearts of certain quadrupeds than in man, and in fetal life it may serve to direct blood from the superior cava into the atrioventricular opening.

**RIGHT VENTRICLE**

The right ventricle occupies a large triangular part of the anterior or sternocostal surface of the heart and extends from the right atrium almost to the apex (Fig. 7-28). Its right boundary on the surface is the coronary sulcus, while its left is the anterior longitudinal sulcus. Superiorly, the part of the right ventricle called the **conus arteriosus** joins the pulmonary trunk. Inferiorly its wall forms the acute margin of the heart and extends for some distance around the diaphragmatic surface. The wall of the right ventricle is thickest near the base of the heart and gradually becomes thinner toward the apex. The right ventricular wall is about one-third the thickness of that forming the left ventricle,

but their capacities are the same, about 85 ml (Latimer, 1953).

The interior of the right ventricle presents a number of openings and specialized parts (Figs. 7-29; 7-30) that require further description.

**RIGHT ATRIOVENTRICULAR ORIFICE.** This opening or **ostium** is a large oval aperture through which the right atrium communicates with the right ventricle (Figs. 7-28; 7-29). It measures about 4 cm in diameter and is large enough to admit the tips of four fingers. It is surrounded by a strong fibrous ring that is covered by the endocardial lining of the heart, and it is guarded by the right atrioventricular or tricuspid valve.

**RIGHT ATRIOVENTRICULAR VALVE.** The right atrioventricular or **tricuspid valve** encircles

**Fig. 7-29.** The interior of the right and left ventricles to show the atrioventricular and pulmonary valves.

**Fig. 7-30.** The atrioventricular, pulmonary, and aortic valves of the heart viewed from above after removal of the atria as well as the pulmonary trunk and aorta.

the right atrioventricular orifice and is notched into three roughly triangular leaflets or cusps. These are attached to the right ventricular wall, and when the valve opens, the cusps project into the ventricle. The three cusps are named **anterior**, **posterior**, and **septal**, and they are of unequal size (Figs. 7-28 to 7-30).

The **anterior** (or infundibular) **cusp** is the largest (Figs. 7-28; 7-29) and is interposed between the atrioventricular orifice and the anterior wall of the right ventricle, to which it is attached in the region of the conus arteriosus (or infundibulum). The **posterior** (or marginal) **cusp**, which is the smallest, extends from the atrioventricular orifice to the ventricular wall adjoining the sternocostal and diaphragmatic surfaces, sometimes called the acute margin of the heart (Fig. 7-29). The **septal** (or medial) **cusp** extends between the interventricular orifice and the right side of the interventricular septal wall. Small intercalated leaflets may occur between the three larger ones (Fig. 7-29).

Each cusp is composed of strong fibrous tissue that is thick in the central part, but thin and translucent near the margin. The bases of the cusps are attached to the fibrous ring surrounding the atrioventricular orifice, while their apices project into the ventricu-

lar cavity. The atrial surface of the leaflets is smooth, but the ventricular surface is more irregular and the free border of each cusp presents a ragged edge for the attachment of delicate tendinous cords called the **chordae tendineae**. In addition to their attachment to the cusps, the chordae tendineae are secured to papillary muscles in the ventricle. This makes the valve as a whole competent enough to withstand the back pressure of the blood during ventricular systole, thereby preventing the regurgitation of blood into the atrium.

**CHORDAE TENDINEAE.** These strong fibrous cords are delicate but inelastic. They are attached to the ventricular end of the valve cusps at their apices and margins, and then are anchored to the muscular ventricular wall. They number about twenty and are of different length and thickness. The majority are attached to projections of the **trabeculae carneae** called **papillary muscles** (Figs. 7-28; 7-29).

**TRABECULAE CARNEAE.** The trabeculae carneae are irregular bundles and bands of muscle that project from the entire inner surface of the ventricle except at the conus arteriosus, where the surface is smooth (Fig. 7-28). They are of three types: some are attached along their entire length to form

ridges on the inner ventricular wall; others are fixed at their two extremities to the heart wall and extend across the lumen for short distances; and still others form the more specialized structures called **papillary muscles**, which project from the heart wall at one end and attach to the chordae tendineae at the other (Fig. 7-28). Although the inner surface of the conus arteriosus is quite smooth, its limit is marked by a ridge of muscular tissue, the **supraventricular crest**, which extends across the dorsal ventricular wall toward the pulmonary trunk from the attachment of the ventral cusp at the atrioventricular ring (Fig. 7-29).

The **septomarginal trabecula** is a stout bundle of heart muscle in the central or apical part of the right ventricle. It crosses the ventricular lumen from the base of the anterior papillary muscle to the interventricular septum (Fig. 7-28). It is of variable size and constancy in the human heart, but is more prominent in some larger mammals where it is supposed to resist overdistention of the ventricle. For this reason it is also called the **moderator band**. When present, it usually contains the right limb of the atrioventricular conduction bundle (Truex and Copenhaver, 1947).

**PAPILLARY MUSCLES.** The papillary muscles are conical projections of ventricular muscle, the apices of which afford attachment to the chordae tendineae. Although their size and number are somewhat variable, the two principal ones are named the anterior and posterior papillary muscles.

The **anterior papillary muscle** is the larger of the two prominent papillary muscles, protruding partly from the anterior and partly from the septal wall of the right ventricle (Fig. 7-28). Its chordae tendineae are attached to the anterior and posterior cusps of the tricuspid valve, and frequently a portion of this muscle constitutes the moderator band.

The **posterior papillary muscle** usually consists of two or three parts which arise from the posterior ventricular wall and to which are attached the chordae tendineae of the posterior and septal cusps. Another small papillary muscle arises near the septal end of the supraventricular crest. It is called the *papillary muscle of the conus arteriosus*, and it is attached to the anterior and septal cusps. Other small *septal papillary muscles* spring directly from the interventricular sep-

tum and attach to individual chordae tendineae.

**ORIFICE OF THE PULMONARY TRUNK.** At the summit of the conus arteriosus is a circular opening leading to the pulmonary trunk (Figs. 7-28; 7-29). It is close to the interventricular septum, above and to the left of the atrioventricular aperture, and is guarded by the pulmonary valve.

**PULMONARY VALVE.** This valve consists of three **semilunar cusps** (or valvula) formed by duplications of the endocardial lining which are reinforced by fibrous tissue (Figs. 7-28 to 7-30). They are attached by their curved margins to the wall of the pulmonary trunk at its site of junction with the conus arteriosus. The free borders of the cusps are directed upward toward the lumen of the pulmonary trunk. Behind each cusp, that is, between the cusp and the wall of the pulmonary trunk, is a pocket called the **pulmonary sinus** (sinus of Valsalva<sup>1</sup>). The point at which the attachments of two adjacent cusps come together is called a **commissure**. Each cusp is marked by a small thickened fibrocartilaginous **nodule** (corpus of Arantius<sup>2</sup>) at the center of the free margin. From the nodule tendinous fibers radiate through the cusps to the commissure of attachment. These strengthen both the free and attached margins of the cusp. Two thin crescentic arcs, free of fibers, are placed one on each side of the nodule immediately adjoining the free margin. These are called the **lunules**. The line of contact between the cusps, when the valve is closed, is not at the free margin, but by the nodule and lunulae.

The three semilunar cusps forming the pulmonary valve are named the **right** (right anterior), **left** (posterior), and **anterior** (left anterior).

Two methods are used to name the semilunar cusps of the pulmonary valve. One is based on their position in the adult body. The other, and currently recommended terminology in the *Nomina Anatomica*, is based on the position of the cusps in the fetus prior to rotation of the pulmonary artery and the aorta. In this book, the latter terminology has been presented as preferred and is printed in **bold type** above, while the former terminology is shown in parentheses.

<sup>1</sup>Antonio M. Valsalva (1666-1723): An Italian anatomist.

<sup>2</sup>Giulio C. Arantius (1530-1589): An Italian physician and anatomist.

**LEFT ATRIUM**

The left atrium is rather smaller than the right and the wall is thicker, measuring about 3 mm. It forms a large part of the base and dorsal part of the heart (Figs. 7-26; 7-27). Its separation from the right atrium is not identifiable on the posterior heart surface except when the organ is distended, but the aorta and pulmonary trunk lie between the two atria on the anterior surface. The left atrium consists of two parts, a **principal cavity** and the **left auricle**.

**PRINCIPAL CAVITY.** The principal cavity of the left atrium contains the openings of the four pulmonary veins, two on each side of the chamber, and they are not guarded by valves. Frequently the two left veins have a common opening. Additionally, the principal cavity opens into the left ventricle by means of the left atrioventricular orifice, which is a little smaller than the right and is guarded by the **left atrioventricular** or **mitral valve**. The surface of the principal cavity is smooth. The interatrial septum contains a depression that is bounded below by a crescentic ridge. This is the edge of the **valve of the foramen ovale**, the remnant of the septum primum which became fused over the opening of the foramen ovale at birth.

**LEFT AURICLE.** The left auricle is somewhat constricted at its junction with the principal cavity. It is longer, narrower, and more curved than the right auricle, and its margins are more deeply indented. It curves anteriorly around the base of the pulmonary trunk, only its tip being visible on the sternocostal aspect of the heart (Fig. 7-25). At this site it also overlies the commencement of the left coronary artery. The inner surface of the auricle is marked by muscular ridges, similar to those in the right auricle, called **musculi pectinati**.

**LEFT VENTRICLE**

The left ventricle occupies a small part of the sternocostal and about half of the diaphragmatic surface of the heart (Figs. 7-25; 7-26). It forms part of the left margin of the heart and its tip forms the apex. The left ventricle is longer and more conical in shape than the right, and its walls are about three times as thick. In a cross section its cavity is

oval or circular in outline. The interior presents two openings: the atrioventricular orifice guarded by the mitral valve and the aortic aperture guarded by the aortic valve.

**LEFT ATRIOVENTRICULAR ORIFICE.** The left atrioventricular orifice is located below and somewhat posterior to the aortic opening. It is smaller than the corresponding orifice in the right heart and its breadth allows only two fingers to pass. It is surrounded by a dense fibrous ring that supports the **left atrioventricular valve**, which is also called the **mitral** or **bicuspid valve**.

**LEFT ATRIOVENTRICULAR VALVE.** The left atrioventricular or mitral valve is attached to the fibrous ring surrounding the circumference of the left atrioventricular orifice. It is bicuspid, and its two cusps, which are of unequal size, extend down into the left ventricle in a manner similar to those of the valve on the opposite side (Fig. 7-29). The cusps are named anterior and posterior according to their position in the ventricle.

The larger **anterior cusp** is placed ventrally and to the right, adjacent to the aortic opening. The smaller or posterior cusp is located behind and to the left of the aortic aperture. Two smaller cusps are sometimes found at the angles of junction between the main cusps. The chordae tendineae are thicker and stronger, but less numerous than those in the right ventricle (Fig. 7-29).

**TRABECULAE CARNEAE.** There are three types of trabeculae carneae, similar to those described for the right ventricle, but they are more numerous and more densely packed, especially at the apex and on the dorsal wall.

**PAPILLARY MUSCLES.** There are two principal papillary muscles in the left ventricle. One is attached to the anterior or sternocostal wall and is therefore called the **anterior papillary muscle**. The other, attached to the posterior or diaphragmatic wall, is the **posterior papillary muscle**. Both are of large size and end in rounded extremities to which the chordae tendineae are attached. Each papillary muscle has chordae tendineae which go to both cusps of the valve.

**AORTIC ORIFICE.** The aortic opening is a circular aperture located anterior and to the right of the atrioventricular orifice, from which it is separated by the anterior cusp of the mitral valve. The aortic orifice is guarded by the **aortic valve**, which consists of three semilunar cusps. It is slightly over 2.5 cm

(one inch) in diameter, and the portion of the ventricle immediately adjacent to the orifice is termed the **aortic vestibule**, which consists largely of fibrous tissue rather than cardiac muscle.

**AORTIC VALVE.** The aortic valve is composed of three semilunar cusps, similar to those of the pulmonary valve but larger, thicker, and stronger (Fig. 7-31). The cusps surround the aortic orifice and they contain **lunules** that are more distinct and nodules that are thicker and more prominent than those of the pulmonary valve. Between the cusps and the aortic wall there are dilated pockets called the **aortic sinuses** (of Valsalva), which are larger than those of the pulmonary trunk, and from the aortic wall bounding two of these sinuses the coronary arteries take origin.

The cusps of the aortic valve are named **posterior** (right posterior), **right** (anterior), and **left** (left posterior), based on the embryological development of the aortic septum by division of the truncus arteriosus into the aorta and pulmonary trunk. (In parentheses are the names of the cusps according to their position in the adult heart, but this is no longer recommended by the *Nomina Anatomica*.) The preferred terminology (in

**bold face above**) is consistent with that used for the pulmonary valve and has the added correlation that behind the left and right cusps, the coronary arteries arise from the aorta. The posterior cusp, therefore, would be the non-coronary cusp.

**INTERVENTRICULAR SEPTUM.** The left ventricle is separated from the right ventricle by the interventricular septum. This septum is directed obliquely backward and to the right, and it also has a curvature with convexity to the right, thus completing the oval of the thick left ventricle and encroaching on the cavity of the right ventricle. Its margins correspond to the anterior and posterior interventricular sulci. The greater part of it is thick and muscular and is called the **muscular part** of the interventricular septum. The upper portion of the interventricular septum, which separates the aortic vestibule from the lower part of the right atrium and the upper part of the right ventricle, is thinner and fibrous and is called the **membranous part** of the interventricular septum. This is the last part of the septum to close in embryological development (Fig. 7-17) and is the usual site of the defect in a condition known as *patent interventricular septum*.

**Fig. 7-31.** The aortic entrance from the left ventricle has been opened to show the three semilunar cusps of the aortic valve. Within the ventricle a part of the left atrioventricular (mitral) valve is also exposed.

## Structure of the Cardiac Wall

The wall of the heart consists principally of **cardiac muscle** and a **fibrous skeleton**, the latter serving, in part, for the attachment of some cardiac muscle fibers and the heart valves. The heart wall is covered by mesothelial linings, both externally by the **epicardium** and internally by the **endocardium**.

**FIBROUS CARDIAC SKELETON.** The fibrous skeleton of the heart consists of fibrous or fibrocartilaginous tissue which surrounds the atrioventricular, aortic, and pulmonary apertures with fibrous rings. This more resistant tissue merges with the membranous part of the interventricular septum and serves for the attachment of valves and heart muscle fibers. In the heart of certain large animals, such as the ox, this fibrous tissue may contain cartilage and even bone. Between the right margin of the **left atrioventricular ring**, and the **aortic ring** and **right atrioventricular ring**, the dense tissue forms a triangular mass, the **right fibrous trigone** (Fig. 7-32). This mass also forms the basal thickening of the membranous septum. A fibrous band from the right trigone and right atrioventricular ring to the posterior side of the conus arteriosus and anterior aspect of the aortic ring is called the **tendon of the conus**. A similar but smaller mass of fibrous tissue, the **left fibrous trigone**, lies between the aortic and left atrioventricular rings. The atrioventricular rings and the trigones separate the muscular walls of the atria from those of the ventricles. The bundles of mus-

cular fibers of both chambers, however, use the fibrous tissue for their attachment.

**HEART MUSCULATURE.** The muscular structure of the heart consists of bands of fibers that present an exceedingly intricate interlacement. Distinct bundles of muscle fibers form the walls of the atria and the ventricles, but those bundles forming the atrial chambers are functionally separated from those forming the ventricles by the fibrous rings. An additional special bundle of muscle fibers, the **atrioventricular bundle** (of His<sup>1</sup>), which forms the conducting system of the heart, does constitute a functional connection between the atrial and ventricular chambers and will be discussed separately.

The **musculature of the atria** can be dissected into the two layers, superficial and deep. The more *superficial bundles* extend across both atria, encircling them in single or double loops. The *deeper bundles* are more generally confined to each atrium, although some fibers pass through the interatrial septum to encircle the other atrium as well. The atrial bundles are attached to the fibrous trigones and the atrioventricular rings, and they extend for short distances to encircle the roots of the venae cavae on the right side and the pulmonary veins on the left.

The **musculature of the ventricles** consists of bundles that probably all arise from the fibrotendinous structures at the base of the heart, converge in spiral courses toward the apex for varying distances, and then turn spirally upward to be inserted on the opposite side of these same fibrotendinous structures. The **superficial bundles** spiral to their vortex at or near the apex of the left ventricle before they turn

<sup>1</sup>Wilhelm His, Jr. (1863-1934): A German anatomist (Leipzig and Berlin).

**FIG. 7-32.** The fibrous skeleton of the heart. The atria have been removed and the heart is viewed toward the ventricles. (Redrawn from Tandler, 1912.)

upward, while the **deeper bundles** turn upward at varying distances without reaching the apex.

The *superficial bulbospiral bundle* arises from the conus arteriosus, left side of the aortic septum, aortic ring, and left atrioventricular ring, and passes toward the apex of the heart. At their origin the fibers form a broad thin sheet that becomes thick and narrow at the apex where the bundle twists on itself. It then continues upward and posteriorly in a spiral manner on the inner surface of the left ventricle, spreading out into a thin sheet that is inserted on the opposite side of the fibrotendinous structures from which it arose. These fibers nearly make a double circle that is open at the top, somewhat like a figure 8, around the heart. As the fibers pass toward the apex they lie superficial to the deep bulbospiral bundle, and as they pass upward from the apex they partly blend and partly pass on the inner side of the deep bundle in directions nearly at right angles to the descending superficial fibers.

The *superficial sinuspiral bundle* arises as a thin layer from the posterior aspect of the right and left atrioventricular rings. The fibers pass more horizontally around the heart to the apex than do those of the superficial bulbospiral bundle. They encircle the right ventricle and converge as they approach the apex, passing upward into the papillary muscles on the inner wall of the ventricles. They become attached to the fibrous rings either by way of the chordae tendineae or directly by the fibers themselves.

The *deep bulbospiral bundle* arises immediately beneath the superficial bulbospiral bundle from the left side of the aortic and left atrioventricular rings. The fibers pass downward to the right and enter the septum through the posterior longitudinal sulcus. They then encircle the left ventricle without reaching the apex. Turning upon themselves on the apical side of the ring, they blend with the fibers of the superficial bundle as they pass spirally upward to be inserted on the right side of the fibrous aortic and left atrioventricular rings. These fibers also seem to form an open figure 8, with both loops of about the same size.

The *deep sinuspiral bundle* is more especially concerned with the right ventricle, although its fibers communicate freely with the papillary muscles of both ventricles. Its fibers arise from the posterior part of the left atrioventricular ring and pass diagonally into the deeper layer of the wall of the right ventricle, where they turn upward to the conus arteriosus and membranous part of the interventricular septum.

The *interventricular bundles* are represented in part by the longitudinal bundle of the right ventricle, which passes through the interventricular septum and must be cut in order to unroll the heart, and in part by the interpapillary bands. The *circular bands of the conus* simply extend from one side of the tendon of the conus arteriosus around the root of the pulmonary trunk and conus to the opposite side of the tendon.

## Conduction System of the Heart

The conduction system of the heart consists of the sinoatrial node, the atrioventricular node, the atrioventricular bundle, and the terminal conducting fibers or Purkinje<sup>1</sup> fibers. Although these structures differ from each other in certain details, they are all composed of specially differentiated cardiac muscle fibers that have the capacity to conduct electrical impulses and thus are more highly developed than fibers in the rest of the heart. The musculature of both the ventricles and the atria has an intrinsic capability to contract spontaneously, independent of any nervous influence. The conduction system, however, initiates and superimposes a rhythmicity to this contraction, which has a rapid rate and is transmitted to all parts of the heart. The rate of the cardiac rhythm is regulated by the autonomic nerves which are under the control of the central nervous system.

**SINUATRIAL NODE.** The sinoatrial node (S-A node) is a small mass of specialized heart muscle situated in the crista terminalis at the junction of the superior vena cava and right atrium. It receives its name from the fact that this region develops from the margin of the sinus venosus in the embryo. The sinoatrial node consists of very narrow fusiform muscle fibers, which are assembled in a crescent-shaped region less than a centimeter in length and slightly more than a millimeter in breadth. The node is difficult to identify from surrounding muscle tissue at dissection, but may be located by tracing the course of the small sinunodal artery, which usually branches from the right coronary artery and supplies the region. The contraction of the heart is initiated by the node, and it is therefore called the **pacemaker of the heart**. No specialized bundle for the conduction of the impulses from this node to the ventricle has, as yet, been identified morphologically. The fibers of the node merge with the surrounding atrial muscle fibers, and these alone appear to be responsible for transmitting the contractile wave across the atria and the impulses to the atrioventricular node.

<sup>1</sup>Johannes E. Purkinje (1787-1869): A German and then Czechoslovakian anatomist (Breslau and Prague).

**ATRIOVENTRICULAR NODE.** The atrioventricular node (A-V node) is slightly smaller than the sinuatrial node and lies near the orifice of the coronary sinus in the septal wall of the right atrium (Fig. 7-33). Its muscle fibers, not being encapsulated by connective tissue, can seldom be recognized except that they are continuous with those of the atrioventricular bundle below and the atrial musculature above. The node is supplied by autonomic nerve fibers and usually receives its blood supply from the posterior interventricular artery.

**ATRIOVENTRICULAR BUNDLE.** The atrioventricular bundle (A-V bundle) begins at the atrioventricular node and follows along the membranous part of the interventricular septum toward the left atrioventricular opening, a distance of about one centimeter. Toward the middle of the septum, the A-V bundle splits into right and left crura, which straddle the summit of the muscular part of the interventricular septum. The **right crus** of the A-V bundle continues under the endocardium toward the apex, spreading to all parts of the right ventricle (Fig. 7-33). It

breaks up into small bundles of fibers called the **terminal conducting Purkinje fibers**, which become continuous with the cardiac muscle fibers of the right ventricle. A large fascicle of terminal fibers enters the **septomarginal (or moderator) band**, if this is present, to reach the opposite wall of the ventricle and the anterior papillary muscle. The **left crus** of the A-V bundle penetrates the fibrous septum and comes to lie just under the endocardium of the left ventricle (Fig. 7-34). At first it is a flattened band which soon fans out on the septal wall more quickly than the right crus and breaks up into bundles of the terminal conducting Purkinje fibers, which are distributed throughout the left ventricle.

The two crura are surrounded by more or less distinct connective tissue sheaths and may be visible, therefore, on gross examination of the heart. They are more easily seen in a fresh specimen than in a preserved one, and the left branch frequently shows more clearly than the right. The bundle and branches may be demonstrated by injecting India ink into the connective tissue sheath of

**FIG. 7-33.** The conduction system of the heart. The interior of the right side of the heart has been opened to show (in yellow) the right crus of the atrioventricular bundle (of His).

**Fig. 7-34.** The left crus of the atrioventricular bundle exposed after opening the left ventricle. The aorta has been opened to reveal the cusps of the aortic valve and the membranous part of the interventricular septum.

a fresh specimen, a procedure that is particularly effective with a sheep or ox heart.

The terminal conducting Purkinje fibers are different histologically from the nodal fibers, merging with the nodal tissue at one end of the A-V bundle and with the regular heart muscle at the other. The individual fibers can only be identified with the aid of a microscope. Coursing initially in small bundles under the endocardium, they then penetrate and ramify as individual fibers throughout the ventricular musculature.

### CARDIAC CYCLE

The complete cardiac cycle commences at the end of one heart contraction and extends to the end of the next contraction. It therefore includes first a period of cardiac relaxation called **diastole**, which is then followed by the contraction phase called **systole**. Because each cardiac muscle fiber possesses the ability to contract rhythmically, it remains the important function of the conducting system of the heart to initiate the contraction wave, which has its initial site of generation at the sinoatrial node. After spreading across the atria, the contraction wave allows the muscle fibers of both atria to contract as a unit. Then, after the electrical impulse reaches the

atrioventricular node, the conduction system of the heart transmits it through both ventricles, causing the cardiac muscle fibers forming the walls of these chambers to contract efficiently and in unison. It is the changes in pressure within the chambers, caused by the contraction and relaxation of the cardiac muscle, that open and close the atrioventricular valves as well as the pulmonary and aortic valves. Closure of the valves accounts for the audible heart sounds that can be heard over the anterior chest wall.

The graphic representation of the electrical action currents in the heart that can be recorded from the body surface is the commonly used electrocardiogram (Fig. 7-35). Each cardiac cycle, when visualized on the electrocardiogram, is seen to consist of P, QRS, and T waves. The **P wave** is generated by the spread of depolarization from the sinoatrial node across the two atria. Atrial contraction soon occurs, causing blood to flow through the open atrioventricular valves. Approximately 0.16 seconds after the onset of the P wave, the electrocardiogram displays the **QRS wave complex**. This signals that the depolarization wave is spreading across the two ventricles, causing them to contract and thereby to elevate intraventricular pressure. The **first heart sound** is caused by the simultaneous closure of the two atrioventricular valves as ventricular pressure exceeds atrial pressure. Closure of the atrioventricular valves and continued ventricular contraction force the

**Fig. 7-35.** Events in the cardiac cycle shown in a diagrammatic manner. The upper three traces show aortic, atrial, and left ventricular pressure in millimeters of mercury. The bottom trace is the corresponding electrocardiogram showing the P, QRS, and T waves. This diagram carries the cardiac cycle through two systoles, interrupted by a diastole. (Modified from Guyton, 1974.)

valves of the pulmonary artery and aorta to open and blood to flow into these vessels. Slightly before the end of ventricular contraction, the electrocardiogram displays the **T wave**, which represents the initiation of the phase of ventricular relaxation. As a result of blood leaving the ventricles and with the completion of ventricular contraction, the pulmonary and aortic valves close, causing the shorter but sharper **second heart sound**. With continuing diminished ventricular pressure, the atrioventricular valves open and the cycle is repeated.

## Histology and Ultrastructure of Cardiac Muscle

The myocardium is composed of muscle fibers that show many similarities to the fibers of striated muscle (Fig. 7-36). Cardiac muscle fibers consist of myofibrils that are separated by sarcoplasm, and they also show **A, I, Z, H, and M transverse striations**. For many years it was thought that cardiac muscle was not composed of individual muscle cells, but that the cardiac fibers were joined in such a way as to form a syncytium. Ultrastructural studies have shown this not to be true. It is now recognized that the **intercalated discs** that cross cardiac muscle fibers in a transverse manner represent sites where individual muscle fibers are joined in an end-to-end arrangement of interdigitating membranes and show specialized surface membrane complexes (Fig. 7-38).

Cardiac muscle fibers are oriented in parallel columns similar to skeletal muscle; however, unlike skeletal muscle, cardiac fibers tend to bifurcate and anastomose (Fig. 7-36). Another difference between skeletal

and cardiac muscle is the fact that the elongated nuclei of heart muscle fibers lie deep within the substance of the muscle cells rather than directly beneath the sarcolemma of the fiber as is seen in skeletal muscle (Fig. 7-37). Between adjacent cardiac fibers is found loose connective tissue containing nerve fibers and an abundance of capillaries and lymphatics. The myofibrillar substructure of cardiac fibers consists of both myosin and actin myofilaments, accounting for the similarity of the transverse striations to those observed in skeletal muscle.

Cardiac muscle fibers show a great abundance of large **mitochondria**, presumably because of the high metabolic and energy requirements of the tissue (Fig. 7-38). The sarcoplasm is also rich in glycogen and lipids, helping to serve the energy resources of the muscle fibers. Invaginations of the sarcolemma of heart muscle fibers give rise to a **T system** which, similar to skeletal muscle, allows the internal structure of cardiac fibers to be more closely related to the extracellular space. In heart muscle, however, the transverse tubules are found at the Z line rather than at the A-I junctions and they are somewhat wider in diameter than those of skeletal muscle. The **sarcoplasmic reticulum** is neither as elaborate nor as abundant as that in skeletal muscle (Fig. 7-39). Although the sarcoplasmic reticulum network extends over the surface of the myocardial sarcomere, terminal cisterns similar to those of skeletal muscle are not seen. In their place are small cisternal expansions that are more irregularly placed and come into individual contact with the T tubular membrane to form a dyad coupling, in contrast to the triad configuration seen in skeletal muscle.

Intercalated discs have long been recognized as a characteristic microscopic feature of cardiac muscle fibers. They are easily identified by the light microscope in ordinary hematoxylin and eosin sections, and their visibility may even be enhanced by special stains. Electron micrographs have revealed that the darkly stained intercalated discs observed with the light microscope are junctional intercellular complexes between adjacent cardiac muscle fibers (Fig. 7-40). At the intercalated disc, apposed surfaces of the cardiac fibers are covered by their own cell membranes, which are joined together by specialized complexes that maintain intercellular cohesion. The **transverse parts** of

intercalated discs are arranged in a stepwise fashion, crossing the fibers at right angles, while the **lateral parts** of the discs are longitudinally oriented and seen to course parallel to the myofibrils.

**CONDUCTION SYSTEM.** The **sinuatrial node** consists of slender fusiform cells largely filled with sarcoplasm but containing a few striated fibrillae. The cells are smaller than the surrounding atrial muscular fibers and they are intermeshed in connective tissue and arranged, more or less, in a parallel manner and in relation to the nodal artery. At the periphery of the node the fusiform nodal fibers merge with the atrial musculature. Closely associated with the sinuatrial node are a number of parasympathetic ganglia associated with the vagus nerve, but there are also postganglionic sympathetic fibers nearby. The **atrioventricular node** is a small mass of slender specialized cells found in the lower part of the interatrial septum. Its fibers are branched and irregularly arranged, and they merge with the atrial musculature on the one hand and continue into the atrioventricular bundle on the other. In the atrioventricular bundle and its first two branches, the specialized fibers remain slender, but in the more peripheral branches of the A-V bundle the fibers assume the histo-

**FIG. 7-36.** Longitudinal section of human cardiac muscle fibers showing their branching manner. 400  $\times$  magnification. (From Rauber-Kopsch, 1955.)

**FIG. 7-37.** Cross section of human cardiac muscle showing the nuclei located deeply within the interior of the fibers rather than immediately beneath the sarcolemma as is seen in skeletal muscle. (From Rauber-Kopsch, 1955.)

**FIG. 7-38.** Electron micrograph of cardiac fibers in longitudinal section. The cells are joined end-to-end by a typical steplike intercalated disc (InD). Mitochondria (Mt) divide the contractile substance, and lipid droplets are found between the ends of the mitochondria. (From Fawcett, D. W., *The Cell, An Atlas of Fine Structure*, W. B. Saunders Co., 1966.)

**Fig. 7-39.** The sarcoplasmic reticulum (SR) consisting of a simple network of anastomosing tubules. The section passes tangential to the inner surface of a mass of myofilaments (M), and the sarcoplasmic reticulum continues across the Z line (Z arrow) without terminal cisternae (From Fawcett and McNutt, *J. Cell Biol.*, 42:1-45, 1969.)

logical characteristics of the Purkinje fibers. These latter fibers are larger in diameter than ordinary cardiac muscle. They contain relatively few peripherally placed myofibrillae, have abundant sarcoplasm, and the centrally placed nuclei are larger and more vesicular than those of the usual cardiac muscle. As the ramifications of the bundles spread into the ventricular wall, the individ-

ual Purkinje fibers become continuous with fibers of the main cardiac musculature.

**VESSELS AND NERVES.** The arteries supplying the heart are the right and left coronary arteries, and the veins are mostly tributaries of the coronary sinus. The lymphatics consist of deep and superficial plexuses, which form right and left trunks and end in the tracheobronchial nodes. Detailed descriptions of the blood vessels and lymphatics of the heart can be

**Fig. 7-40.** Electron micrograph of restricted region of the transverse portion of an intercalated disc. The cell surfaces at the disc are approximately 200 to 300 Å apart. Actin filaments are seen to enter accumulations of dense material in the sarcoplasm subjacent to the cell membrane. Other actin filaments near the disc are seen coursing transverse to the prevailing direction of the myofilaments (at arrows). 70,000 × (From Fawcett and McNutt, *J. Cell Biol.*, 42:1-45, 1969.)

found in the chapters dealing with these systems.

The **nerves** that supply the heart are cardiac branches of the vagus nerve and sympathetic trunks. These nerves join to form the cardiac plexuses and their ramifications, the coronary plexuses, which accompany the coronary arteries. The sympathetic fibers are postganglionics from the cervical and upper thoracic ganglia. The vagus fibers are preganglionics, whose ganglion cells form clusters in the connective tissue of the epicardium of the atria and the interatrial septum. The autonomic innervation of the heart is described in more detail in the chapter on the nervous system.

### CONGENITAL MALFORMATIONS OF THE HEART

Developmental abnormalities may result from the suppression or overgrowth in varying degrees of the individual parts of the heart. The more prevalent abnormalities, however, are the result of partial failure in the partitioning of the heart. **Interatrial defects** that allow the passage of a probe through the foramen ovale are quite common (20%), but are of no functional significance. Larger defects of the septum are less common and may involve the atrial or ventricular septa or both. Abnormality in the growth of the septum and the endocardial cushions responsible for separating the truncus arteriosus into the aorta and pulmonary trunk results in what are called transposition complexes. **Transposition** refers to a shifting of the arterial trunks from their proper ori-

gins. The abnormalities are designated according to the degree of displacement as (a) overriding, (b) partial transposition, and (c) complete transposition. In *overriding*, one of the arterial trunks straddles the ventricular septum in which there is a defect. In *partial transposition*, both arterial trunks arise from the same ventricle. In *complete transposition*, the aorta arises from the right ventricle and the pulmonary trunk from the left ventricle. When abnormalities occur, they are often seen in groups or complexes. One of the better known complexes, called the tetralogy of Fallot,<sup>1</sup> has a combination of the following four abnormalities: (1) overriding of the aorta, (2) a defect in the ventricular septum, (3) pulmonary stenosis, and (4) hypertrophied right ventricle. The **Eisenmenger complex**<sup>2</sup> is similar to the tetralogy, having (1) an overriding aorta, (2) septal defect, (3) hypoplasia of the aorta, and (4) right ventricular hypertrophy. These and many other congenital malformations of the heart interfere with the pumping of the proper amount of blood into the pulmonary circulation. In consequence, the blood sent into the systemic arteries is poorly oxygenated, the predominance of venous blood causes cyanosis, and the individual is popularly known as a "blue baby." Detailed descriptions of cardiac anomalies have been published by Gould (1953), Lev (1953), and Gray and Skandalakis (1972).

## The Arteries

After reaching the ventricles of the heart, blood is then propelled to all parts of the body through the arteries. Two large arteries leave the heart: the **pulmonary trunk** and the **aorta**. The pulmonary trunk divides into a **right** and **left pulmonary artery**, each of which courses transversely in the thorax to its corresponding lung. These vessels subdivide profusely within the lung tissue to form a capillary bed, which exchanges carbon dioxide in the blood for oxygen in the alveoli. The pulmonary arteries, along with the pulmonary veins which return oxygenated blood to the left atrium, constitute the **pulmonary circulation**. The aorta and its many branches also ramify into capillary beds within all the body organs. These arteries and the veins returning blood to the heart form the **systemic circulation**. The continuous ramification of the systemic arteries results in the distribution of capillaries to all the tissues except the nails, epidermis, cornea, mucous membranes, and most cartilage. These latter avascular structures receive their nourishment through the processes of diffusion.

Arteries may show various patterns in their mode of branching. A short trunk may subdivide into several branches at the same point, such as occurs to the celiac and thyrocervical trunks. Several branches may be

given off in succession and the main trunk continue, as in the arteries of the limbs. The division may be dichotomous as at the bifurcation of the abdominal aorta into the common iliac arteries. Although the branches of an artery are smaller than their trunk, the combined cross-sectional area of the two resulting arteries is generally greater than that of the parent trunk before the division. The combined cross-sectional area of all the arterial branches, therefore, greatly exceeds that of the aorta. It has been estimated that the total cross-sectional area of all the capillaries in the body is nearly 1,000 times that of the aorta, from which they derive their arterial blood.

Throughout the body generally the larger arterial branches pursue a fairly straight course, but at certain sites they are tortuous. The facial artery and the arteries supplying the lips, for example, are extremely tortuous, being accommodated to the movements of the parts. The uterine arteries also are coiled and tortuous, allowing them to accommodate the increase in size that the uterus undergoes during pregnancy. The larger arteries usually are deeply placed and occupy other more protected locations such as along the flexor surface of the limbs where they are less exposed to injury.

**ANASTOMOSIS OF ARTERIES.** Arterial branches do not always terminate in capillaries. In many parts of the body they open into branches of other arteries of similar size, forming what are called **anastomoses**. Anastomosis may take place between larger arteries forming vascular arches such as those in the palm of the hand or the arcades of the intestines. At the base of the brain, the two vertebral arteries join to form the basilar artery, while branches from the two internal carotid arteries and the basilar artery freely join to form the vital cerebral arterial circle of Willis.<sup>1</sup> More frequently, however, anastomoses form between smaller arteries of one millimeter or less in diameter. In the limbs, anastomoses are quite numerous around the joints, the branches of an artery above the joint uniting with branches of the vessels below. Definite patterns of anastomosis between neighboring arteries occur throughout the body, but in any single body all the different anastomoses that are de-

<sup>1</sup>Thomas Willis (1621-1675): An English physician (London).

**FIG. 8-1.** A schematic representation of the arterial system in the adult male. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, 10th Ed., Vol. 2, Urban & Schwarzenberg, 1975.)

scribed will not be equally well developed nor will they be easily demonstrable at dissection.

**COLLATERAL CIRCULATION.** When the supply of blood to the distal part of an artery that has been occluded is effected through anastomosis of its branches, the resulting

vascular paths constitute a **collateral circulation**. It is frequently necessary for a surgeon to tie off or ligate an artery in order to prevent excessive bleeding. The anastomoses with branches of adjacent arteries may be more numerous in one part of the artery than in another, and the surgeon will en-

deavor to place his ligature where advantage can be taken of the most numerous or effective anastomoses. Collateral circulation may occur through anastomoses with branches of the proximal part of the same artery or with branches of a large neighboring artery. In some regions, the collateral circulation is free, as it would be if either the radial or ulnar artery of the forearm were ligated. At other sites the collateral circulation might be carried by small arteries only. If the vessels in a part of the body have sustained trauma, and the region can be placed at rest, a small flow of blood through small anastomosing channels will keep the tissues alive until the anastomoses expand. The arteries retain their power of growth throughout life, and over time a small anastomosing artery may enlarge into a main trunk, completely restoring the circulation to the initially injured region.

Arteries in certain parts of the body lack anastomoses and are therefore called **end arteries**. When vessels such as these are blocked by thrombosis or embolism, the tissues of the region are left without blood supply and become necrotic, resulting in a condition called an **infarct**. A prime example of an end artery is the central artery of the retina, occlusion of which results in permanent blindness. The collateral circulation of vessels in other organs may exist only at the capillary level, and if a sudden blockage of a main artery occurs, degeneration of tissue results before revascularization is effective. Notwithstanding the free anastomosing of vessels on the surface of the brain, ineffective collateral circulation exists in the substance of the brain. Blockage of a vessel within the brain, therefore, causes the clinical features of **stroke**. Similar microcirculatory conditions are found in other organs such as the lungs, kidneys, and spleen and at the transitional metaphyseal interface between the diaphysis and epiphysis of a long bone. The capillaries of the heart do anastomose, but this condition becomes more pronounced as individuals age. These anastomoses may not be capable of maintaining life if a major occlusion occurs in the heart of a young person, whereas a comparable occlusion in a much older person may be survived because of the years that the heart has had to develop anastomoses and collateral circulation.

## Development of the Arteries

Blood vessels commence development within the mesoderm of the yolk sac and body stalk by the formation of **blood islands** as early as the third week (about 16 days). Shortly thereafter, spaces appear within the islands, and the angioblasts become arranged in cords and form the endothelial linings of the earliest vessels. These vascular channels then continue to enlarge by endothelial outgrowth and fuse with other nearby developing channels.

The primordium of the aorta appears toward the end of the third week at about the same time as the heart (see Fig. 7-3). Two strands of cells arch dorsally from the endocardial mesenchyme, pass on each side of the foregut invagination, and turn caudally along the neural groove. The strands beside the foregut are the primordia of the first aortic arches and their continuations are the **dorsal aortae**. The latter acquire isolated stretches of lumen at the same time as the lateral hearts, i.e., in embryos with three somites. The arches become patent some time later, at seven or eight somites, just before circulation begins. The umbilical arteries also probably arise independently from mesenchyme. After these main channels have become connected and the circulation is established, however, no further growth appears to be by local differentiation from the mesenchyme.

The circulation becomes functional when the first blood cells are washed out of the blood islands of the yolk sac at about the stage of nine somites, early in the fourth week. At this time the heart is contracting vigorously, capillaries have connected the aortae with the blood islands which, in turn, drain into the vitelline veins, and the blood cells have elaborated hemoglobin. The umbilical arteries and veins also have become connected, and oxygenation of the blood takes place in the primitive placenta. From this time forward, the circulatory system develops by budding from existing trunks, the formation of new capillary networks, and the selection of parts of the network as arteries and veins. As the bulk of an embryonic part increases in size, the capillaries are lengthened. Soon the hemodynamic forces

result in the selection of certain channels as arterioles and arteries and others as venules and veins. Later the pattern of the arteries and veins changes continually according to the growth requirements of the embryo. Not only do some vessels grow larger, but well-established vessels may be superseded by others more favorably placed and, in consequence, either regress or disappear. As the endocardial tubes fuse, beyond the pericardial cavity the ventral parts of the two aortae join to form the **aortic sac**.

**AORTIC ARCHES.** The first aortic arch functions until the neural tube is closed and the pharynx begins to differentiate into pouches (Figs. 8-2; 8-3). As the second pharyngeal pouch forms, a sprout from the aortic sac joins the dorsal aorta passing between the first and second pouches. The first aortic arch diminishes as this **second arch** develops (Figs. 8-4; 8-5). The **third, fourth, and sixth arches** are formed in a similar manner and disappear or become modified into various adult structures. The **fifth arch** is never more than a questionable rudiment in the human embryo.

By the time the embryo is 4 mm in length (toward the latter part of the fourth week), the first arch has about disappeared; the second arch has formed, reached its maximum development, and diminished in size; and the third arch is well developed (Figs. 8-4; 8-5). Sprouts may be present for the fourth and pulmonary (sixth) arches. In a 5-mm embryo (beginning of the fifth week), the third and fourth arches have reached a maximum and the dorsal and ventral sprouts of the pulmonary or sixth arches are nearly joined (Figs. 8-6; 8-7). The pulmonary arches are usually complete in a 6-mm embryo (middle of the fifth week). The right one soon begins to regress and by the end of the fifth week has disappeared in 12- to 13-mm embryos. The third arches also have become incomplete by this time (Figs. 8-8; 8-9; 8-10).

Although the aortic arches do not persist as such, remnants of them remain as important parts of the arterial system (Fig. 8-11). The **first arch**, even at the earliest stages, has an extension into the region of the forebrain, the primordium of the **internal carotid artery** (Figs. 8-5; 8-7). The first arch disappears and

**FIGS. 8-2 and 8-3.** Ventral and lateral views of the cranial portion of the arterial system at about the end of the third week in a human embryo of 3 mm. The first aortic arch is at its maximum development and the dorsal and ventral outgrowths, which are to aid in the formation of the second arch, are just appearing. (From Congdon, 1922.)

**Figs. 8-4 and 8-5.** Ventral and lateral views of an embryo, 4 mm in length, near the end of the fourth week. The first arch has receded, the second is much reduced, and the third well developed. Dorsal and ventral outgrowths for the fourth and probably the pulmonary arch (sixth) are present. (From Congdon, 1922.)

**Figs. 8-6 and 8-7.** Ventral and lateral views of a 5-mm embryo during the early part of the fifth week. The third and fourth arches are in a condition of maximum development. The dorsal and ventral sprouts for the pulmonary arches have nearly met, and the primitive pulmonary arches are already of considerable length. (From Congdon, 1922.)

**Figs. 8-8 and 8-9.** Ventral and lateral views of an 11-mm embryo estimated to be between 33 and 35 days old (about 5 weeks). The pulmonary arches are complete and the right is already regressing. The third arch is bent cranially at its dorsal end. (From Congdon, 1922.)

**Fig. 8-10.** Lateral view of a 14-mm embryo estimated to be between five and six weeks old. The last indications of the aortic arch system are just disappearing. (From Congdon, 1922.)

**FIG. 8-11.** Schematic drawings illustrating the changing nature of the truncus arteriosus, aortic sac, aortic arch arteries, and the dorsal aorta. The vessels that are not shaded or colored are not derived from these structures. A. The first two pairs of aortic arch arteries have largely disappeared. B. The carotid and subclavian vessels are forming. The parts of the dorsal aortae and aortic arches that normally disappear are indicated with broken lines. C. The arterial arrangement after the second prenatal month. D. Sketch of the arterial vessels of a 6-month-old infant. (From Moore, K. L., *The Developing Human*, W. B. Saunders Co., 1973.)

the primitive carotid becomes a cranial continuation of the dorsal aorta. The **second arch** (or hyoid arch artery) also disappears early, but its dorsal end gives rise to the **stapedial artery**, which atrophies in man but persists in some mammals. Passing through the ring of the stapes, the stapedial artery divides into supraorbital, infraorbital, and mandibular branches, which follow the three divisions of the trigeminal nerve. The infraorbital and mandibular arise from a common stem, the terminal part of which anastomoses with the external carotid. On the obliteration of the **stapedial artery**, this anastomosis enlarges and forms the **maxillary artery**. The common stem of the infraorbital and mandibular branches passes between the two roots of the auriculotemporal nerve and becomes the **middle meningeal artery**. The original supraorbital branch of the stapedial artery remains as the small orbital branches of the middle meningeal. The **third** (or carotid) **arch** forms the **common carotid artery** and the first part of the **internal carotid artery**. The proximal segment of this arch is connected with the aortic sac and persists as the common carotid. The remainder of the internal carotid forms from the cranial extension of the dorsal aorta (Fig. 8-11, A and B). The manner of formation of the external carotid artery is not well understood, but portions of it may be contributed by each of the first three arches. The arch itself persists, keeping its connection with the cranial extension of the dorsal aorta, but losing its connection caudally toward the fourth arch (Fig. 8-11, B). The **left fourth arch** persists and provides the basis for the adult **arch of the aorta**, which extends between the aortic sac and the ductus arteriosus. The **right fourth arch** persists as the proximal part of the **right subclavian artery**. Both **fifth arch** vessels are at best rudimentary and disappear early. The **sixth arches** are frequently referred to as the **pulmonary arches**. The proximal or ventral part of the **right sixth arch** persists as the **right pulmonary artery**, while the distal or dorsal part of it degenerates and disappears. The proximal part of the **left sixth arch** becomes absorbed into the **pulmonary trunk**, forming the region of its bifurcation. The distal segment of the left sixth arch persists as the **ductus arteriosus** until after birth, at which time it contracts and gradually be-

comes fibrosed into the **ligamentum arteriosum** (Fig. 8-11, C and D).

**DORSAL AORTAE.** The two dorsal aortae remain separate for a short time, but toward the end of the third week, at about the 3-mm stage, they fuse to form a single trunk caudal to the eighth or ninth somites. The segment of the aorta between the third and fourth arches disappears on both sides. The **left dorsal aorta** becomes the **descending aorta**, continuing caudally from the left fourth arch. The **right dorsal aorta** retains its continuity with the left fourth arch, and the part that extends as far as the seventh intersegmental artery becomes the right subclavian artery (Fig. 8-11, B to D). The part of the right dorsal aorta between the seventh intersegmental artery and its original site of junction with the left dorsal aorta disappears (Fig. 8-11, B). A slight constriction called the **aortic isthmus** is frequently seen in that part of the aorta between the origin of the left subclavian and the attachment of the ductus arteriosus. A more serious congenital narrowing of the aorta at this site results in the malformation called *coarctation of the aorta*.

Changes in the location of the heart during development produce certain changes in the aortic arches. The heart originally lies ventral to the most cranial part of the pharynx. It later recedes into the thorax, drawing the aortic arches with it. On the right side the fourth arch recedes to the root of the neck; on the left it is withdrawn into the thorax. The recurrent laryngeal branches of the vagus nerve originally pass caudal to the sixth or pulmonary arches. When the heart descends into the thorax, the nerves are pulled down by these arches. On the right side, however, the sixth arch disappears, allowing the nerve to slip up to the next arch (i.e., the fourth, because the fifth arch also disappears), and it thus loops around the adult right subclavian artery. On the left side the sixth arch becomes the ductus arteriosus, which in the adult is represented by the ligamentum arteriosum. This explains why the left recurrent laryngeal nerve loops around the ligamentum arteriosum at the part of the aorta to which the ligamentum is attached.

**SUBCLAVIAN AND VERTEBRAL ARTERIES.** Segmental arteries arise from the primitive dorsal aortae and anastomose between succes-

sive segments (Figs. 8-7; 8-9). The **seventh segmental artery** is of special interest because it forms the lower end of the **vertebral artery** and, when the forelimb bud appears, sends a branch to it which becomes the **subclavian artery**. From the paired seventh segmental arteries the entire left subclavian and the greater part of the right subclavian are formed. The **second pair of segmental arteries** accompanies the hypoglossal nerves to the brain and is named the **hypoglossal arteries**. Each sends forward a branch which forms the cerebral part of the **vertebral artery** and anastomoses with the posterior branch of the internal carotid. The two vertebrals unite on the ventral surface of the hindbrain to form the **basilar artery**. Later the hypoglossal artery atrophies and the ver-

tebral is connected with the first segmental artery. The cervical part of the vertebral is developed from a longitudinal anastomosis between the first seven segmental arteries, so that the seventh of these ultimately becomes the source of the artery. As a result of the growth of the upper limb, the subclavian artery increases greatly in size, and the vertebral then appears to spring from it.

Several segmental arteries contribute branches to the upper limb bud and form in it a free capillary anastomosis. Of the segmental branches, only one, that derived from the **seventh segmental artery**, persists to form the **subclavian artery**. The subclavian artery is prolonged into the upper limb during its development and becomes its arterial stem. Although this **axis artery** (Fig. 8-12)

**FIG. 8-12.** Diagram illustrating the embryonic pattern and subsequent development of the arteries to the upper limb. Names in parentheses refer to the adult structures.

is a continuous vessel, its parts are named topographically subclavian, axillary, and brachial as far as the forearm. The direct continuation of the axis artery in the forearm is the anterior interosseous artery. A branch that accompanies the median nerve, called the **median artery**, soon increases in size and forms the main vessel of the forearm, while the anterior interosseous diminishes. Later the radial and ulnar arteries are developed as branches of the brachial part of the stem and, coincidentally with their enlargement, the median artery recedes. Occasionally the median artery persists as a vessel of some considerable size and accompanies the median nerve into the palm of the hand.

**DESCENDING AORTA.** The **segmental arteries** caudal to the seventh develop around the body wall, retaining their segmental character and becoming the **intercostal** and **lumbar arteries**. In the early embryo, paired ventral branches of the aorta grow out on the yolk sac as the **vitelline arteries**. At its caudal end, the ventral branches accompanying the allantois become the **umbilical arteries**. As the gut develops, a number of ventral visceral branches grow into it. At first these are paired, but with the formation of a mesentery the pairs fuse into single stems. These ventral branches are irregularly spaced, and by a process of shifting along a rich anastomosis, the three main trunks, the **celiac**, the **superior**, and the **inferior mesenteric**, are finally selected. Lateral branches of the aorta grow into the mesonephros. The long course of the **testicular** and **ovarian arteries** is the result of the caudal migration of the gonads after their arteries had become established. Later similar lateral branches grow into the suprarenal glands and the kidneys. In this manner the **suprarenal** and **renal arteries** develop.

The primary arterial trunk or **axis artery** of the embryonic lower limb arises from the dorsal root of the umbilical artery and courses along the posterior surface of the thigh, knee and leg (Fig. 8-13). The **femoral artery** springs from the external iliac and forms a new channel along the anterior aspect of the thigh to its communication with the axis artery above the knee. As this channel increases in size, that part of the axis artery (called the **ischiodic artery**) proximal to the communication disappears, except its upper end, which persists as the inferior glu-

teal artery. Two other segments of the axial artery persist: one forms the proximal part of the popliteal artery, and the other forms a part of the peroneal artery (Fig. 8-13).

## Pulmonary Arterial Vessels

The **pulmonary arterial vessels** convey deoxygenated blood, i.e., venous blood, from the right ventricle of the heart to the lungs. Consistent with the relatively thin wall of the right ventricle in comparison to that of the left ventricle, the pulmonary arterial vessels also have walls only one-third the thickness of vessels of comparable size in the systemic arterial circulation. This is explained by the differences in blood pressure within the pulmonary and systemic arterial vessels. In a young adult, the systolic pressure in the systemic arteries is about 120 mm Hg, whereas in the pulmonary arterial vessels the systolic pressure averages between 20 and 25 mm Hg.

The pulmonary arterial vessels decrease in diameter as they divide. The large pulmonary trunk, which originates in the right ventricle, divides into two pulmonary arteries, one directed to each lung. These vessels divide and then subdivide in association with the bronchi, eventually to send arteries to all of the bronchopulmonary segments that form the different lobes of each lung.

### PULMONARY TRUNK

The pulmonary trunk (see Figs. 7-24; 7-25; 8-14) arises from the conus arteriosus of the right ventricle at the pulmonary orifice. Being short (5 cm in length) and 3 cm wide in diameter, and ascending obliquely backward, it passes at first in front of and then to the left of the ascending aorta. In the rounded concavity of the aortic arch at about the level of the fibrocartilage between the fifth and sixth thoracic vertebrae, the pulmonary trunk divides into right and left pulmonary arteries which are of nearly equal size.

**RELATIONS.** The entire pulmonary trunk is contained within the pericardium. It is enclosed with the ascending aorta in a single tube of the visceral layer of the serous pericardium, which is continued up-

**FIG. 8-13.** A diagram illustrating the general development of the arteries of the lower limb. The letter P indicates the position of the popliteus; T, that of the tibialis posterior; H, that of the flexor hallucis longus. (From Senior, 1919.)

ward upon them from the base of the heart. The fibrous layer of the pericardium is gradually lost upon the external coats of the two pulmonary arteries. *Anteriorly*, the pulmonary trunk is separated from the sternal end of the second left intercostal space by the pleura and left lung, in addition to the pericardium. Initially, the pulmonary artery lies ventral to the ascending aorta, and a bit more superiorly, it lies anterior to the left atrium, at a plane behind the ascending aorta. On *each side* of its origin is the auricle of the corresponding atrium and a coronary artery. In the first part of its course, the left coronary artery passes behind the pulmonary trunk.

The superficial part of the cardiac plexus lies above its bifurcation, between it and the arch of the aorta.

**RIGHT PULMONARY ARTERY.** The right pulmonary artery (Fig. 8-14) is longer and slightly larger than the left. Originating at the bifurcation of the pulmonary trunk, it curves around the ascending aorta and proceeds horizontally to the right. In its course toward the lung, the right pulmonary artery lies behind the aorta and superior vena cava and in front of the right bronchus. At the

Fig. 8-14. The arch of the aorta, and its branches. (Insert: Plan of the branches.)

root of the lung it divides into one large branch, the **anterior trunk**, which is the principal but not the only artery to the superior lobe of the right lung, and a somewhat larger **interlobar branch** (Fig. 8-15). The principal vessel to the superior lobe of the right lung crosses in front of the superior lobe bronchus, which in consequence is frequently called the **eparterial bronchus**. The interlobar trunk, after sending one or more other branches to the superior lobe, furnishes the middle and inferior lobe arteries.

The **anterior trunk** divides into *apical*, *posterior*, and *anterior segmental* arteries, which supply the respective bronchopulmonary segments of the upper lobe. Both the

anterior and posterior segmental arteries split into ascending and descending branches (Fig. 8-15).

The **interlobar trunk** lies near the bottom of the horizontal fissure that separates the superior and middle lobes. It represents the continuation of the pulmonary artery as far as the origin of the middle lobe artery, and it supplies one or two important ascending branches to the posterior segment of the superior lobe. These latter vessels arise from the interlobar trunk more deeply in the horizontal fissure and beyond the site where the anterior trunk branches to ascend to the upper lobe.

The **middle lobe artery** is shown (Fig. 8-15)

**Fig. 8-15.** Diagram showing relation of the branches of the pulmonary artery to the bronchi. (Redrawn after Boyden, *Segmental Anatomy of the Lungs*, 1955.)

as a single artery dividing into a *medial* and a *lateral segmental artery*, but it is quite common for the two segmental arteries to arise separately. The lateral segmental artery divides into a posterior and an anterior branch, which supply the lateral bronchopulmonary segment of the middle lobe. The medial segmental artery, which supplies the medial bronchopulmonary segment of the middle lobe, divides into a superior and an inferior branch.

The interlobar artery continues into the inferior lobe of the right lung. Its initial branch to the inferior lobe is the *superior segmental artery*, which supplies the superior bronchopulmonary segment of that lobe. This vessel divides into a lateral branch and a superomedial branch.

The interlobar artery terminates as the *basal segmental artery*, which supplies the four basal segments of the lower lobe. It branches into the *medial basal*, *lateral basal*, *anterior basal*, and *posterior basal segmental arteries*, each of which courses to its respective bronchopulmonary segment. The individual segmental arteries of these four basal segments are quite variable in

their origin and in the number and size of accessory branches.

**LEFT PULMONARY ARTERY.** The left pulmonary artery is shorter and somewhat smaller than the right. It courses horizontally to the left from the bifurcation of the pulmonary trunk, crossing in front of the descending aorta to lie anterior to the left primary bronchus at the hilum of the left lung (Fig. 8-15). In the fetus, the left pulmonary artery is larger and more important than the right because from it branches the ductus arteriosus. In the adult, the ductus has regressed to become a short fibrous cord, the *ligamentum arteriosum*, connecting the left pulmonary artery with the arch of the aorta just distal to the reflection of the pericardium (Figs. 8-14; 8-16). To the left of the ligamentum arteriosum is found the left recurrent nerve, and to the right of the ligamentum is located the superficial part of the cardiac autonomic plexus. Inferiorly the left pulmonary artery is joined to the superior left pulmonary vein by the *ligament of the left vena cava*.

Although the left pulmonary artery has many similarities with the right, it differs in both general and specific details of branch-

**FIG. 8-16.** The ascending aorta and the coronary blood vessels on the sternocostal aspect of the heart. The pulmonary trunk and pulmonary valve have been removed. (Redrawn from Rauber-Kopsch.)

ing. It tends to have more separate branches than the right. Within the oblique fissure, the left pulmonary artery gives off a series of vessels (from four to eight in number) to the upper lobe and does not have a common vessel comparable to the anterior trunk of the right pulmonary artery. Thus, there is no eparterial bronchus at the right hilum.

The apical and posterior bronchopulmonary segments of the superior lobe, which some authors consider to be a single apicoposterior segment, are supplied by separate apical and posterior arteries. The *apical segmental artery* arises from the anterior surface of the left pulmonary artery as the latter arches over the bronchus, and from there the apical segmental artery runs along the bronchus. Rather than a single vessel, there may be two or more branches, one of which may combine with branches to the posterior or anterior segments. The *posterior segmental artery* arises distal to the apical vessel and continues along the bronchus to the posterior segment. The *anterior segmental artery*

may be single or multiple, arising from the superior part of the arched portion of the main artery. Frequently, this segmental artery may have both ascending and descending branches.

The remainder of the left pulmonary artery is named the **interlobar portion**, and it, in fact, supplies the two lingular bronchopulmonary segments of the superior lobe and all five of the segments of the inferior lobe.

The **lingular artery** arises from the anterior or medial part of the interlobar artery, usually as a single branch. It quickly divides into *superior and inferior lingular segmental arteries*, which course to the two lingular segments of the superior lobe. At times these vessels may arise directly from the interlobar portion as separate arteries.

The *superior segmental artery* of the left inferior lobe arises unexpectedly from the interlobar artery between the origin of the apical and posterior arteries (or apicoposterior artery) of the superior lobe and that

of the lingular artery. It divides into three branches, which may combine with or supply branches to other inferior lobe segments.

The remainder of the interlobar artery continues as the **basal artery**. From this vessel branch the *medial basal*, *lateral basal*, *anterior basal*, and *posterior basal segmental* arteries in a pattern somewhat similar to those of the inferior lobe of the right lung. Each of these basal segmental arteries supplies its bronchopulmonary segment.

## The Aorta

The **aorta** is the main trunk of the systemic arteries which convey oxygenated blood to the tissues of the body. At its commencement from the aortic opening of the left ventricle, it is about 3 cm in diameter. It ascends toward the neck for about 5 cm, then arches posteriorly and to the left over the root of the left lung. It descends within the thorax on the left side of the vertebral column and, gradually inclining toward the midline, passes through the aortic hiatus of the diaphragm into the abdominal cavity. Opposite the caudal border of the fourth lumbar vertebra and considerably diminished in size (about 1.75 cm in diameter), it bifurcates into the two common iliac arteries. The parts of the aorta are the **ascending aorta**, the **arch of the aorta**, and the **descending aorta**. The descending aorta is further divided into **thoracic** and **abdominal** portions of the aorta.

### ASCENDING AORTA

The **ascending aorta** (Fig. 8-15) is about 5 cm in length. It is contained within fibrous pericardium and covered by the visceral pericardium, which encloses it in a common sheath with the pulmonary trunk. It commences at the aortic opening found at the base of the left ventricle on a level with the lower border of the third costal cartilage posterior to the left half of the sternum. The ascending aorta initially curves obliquely to the right, being oriented along the axis of the heart. It ascends as high as the upper border of the second right costal cartilage, lying about 6 cm deep to the inner surface of the sternum. At its origin, opposite the cusps of the aortic valve, are three small dilatations called the **aortic sinuses**. At the continuation

of the ascending aorta into the aortic arch, the caliber of the vessel is increased by a bulging of its right wall, called the **bulb of the aorta**.

**RELATIONS.** The commencement of the ascending aorta is surrounded by the pulmonary artery and the right auricle, except anteriorly at the origin of the coronary artery (Fig. 8-14). More superiorly, its *anterior aspect* is separated from the sternum by the pericardium, the right pleura, the anterior border of the right lung, some loose areolar tissue, and the remains of the thymus. *Posteriorly* it rests upon the left atrium and right pulmonary artery, behind which is the right principal bronchus. On the *right side*, the ascending aorta is related to the superior vena cava, which lies partly behind the aorta, and the right atrium. On the *left side* are the left atrium and the pulmonary trunk.

The two arteries derived from the ascending aorta are the vital **right and left coronary arteries**, which supply the musculature and other structures of the heart.

**RIGHT CORONARY ARTERY.** The right coronary artery (Figs. 7-25; 7-26; 8-14; 8-16 to 8-18) arises from the aorta behind the right (anterior) aortic sinus (of Valsalva). It passes to the right and toward the apex, between the conus arteriosus and right auricle, into the coronary sulcus. It follows the sulcus first to the right around the right margin of the heart and then to the left on the diaphragmatic surface. It ends in two or three branches beyond the interventricular sulcus. In its course it supplies small branches to the right atrium, to the right ventricle by way of its **marginal branch**, and to both ventricles on their diaphragmatic surface by means of the **posterior interventricular branch**.

The **atrial branches** of the right coronary artery are directed superiorly to the musculature of the right atrium. One of these, the **sinoatrial nodal artery**, passes between the right atrium and the superior vena cava to supply the sinoatrial node.

The **marginal branch** is quite large and arises from the main artery at the right margin of the heart, and courses along the surface of the right ventricle, along the acute margin, to the apex. It terminates beyond the apex on the posterior surface of the right ventricle. Thus, the marginal branch supplies both the anterior and posterior surfaces of the right ventricle.

The **posterior interventricular branch** of the right coronary artery courses down the

FIG. 8-17. The coronary blood vessels of the diaphragmatic aspect of the heart. (Redrawn from Rauber-Kopsch.)

posterior interventricular sulcus two-thirds of the way to the apex, supplying branches to both ventricles as it descends. It anastomoses with the anterior interventricular branch of the left coronary artery near the apex.

**LEFT CORONARY ARTERY.** The left coronary artery (see Figs. 7-25; 7-26; 8-14; 8-16 to 8-18) arises from the aorta behind the left (left posterior) aortic sinus (of Valsalva). After a short course under cover of the left auricle, it bifurcates into the **anterior interventricular branch** and the **circumflex branch**. In those instances in which the right coronary artery does not supply the sinoatrial node, a small **sinoatrial nodal branch** may be given off by the left coronary artery near its origin.

The **anterior interventricular branch** of the left coronary artery passes to the left between the pulmonary trunk and the left auricle to the anterior interventricular sulcus, which it follows to the apex, supplying branches to both ventricles. It anastomoses

with the posterior interventricular branch of the right coronary artery.

The **circumflex branch** of the left coronary artery follows the left part of the coronary sulcus, running first to the left and then, around the left margin, it courses backward to the diaphragmatic surface of the heart and to the right, reaching nearly as far as the posterior interventricular sulcus. It supplies branches to the left atrium and ventricle. It anastomoses with the right coronary artery.

**VARIATIONS.** The left coronary artery or its descending branch supplying the left ventricle may arise from the left pulmonary artery. This anomaly can be diagnosed clinically and usually leads to death in infancy. Rarely both coronaries arise from the pulmonary artery.

Single coronary arteries have been described. The left coronary may be a branch of the right or both arteries may arise in the same aortic sinus. There may be three coronary arteries, the accessory vessel giving off some of the branches usually derived from the normal coronary arteries.

**FIG. 8-18.** The coronary arteries (in red) and the cardiac veins (in black). The more intensely colored vessels are shown on the sternocostal surface of the heart, while those on the diaphragmatic surface are shown in lighter shades. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban and Schwarzenberg, Munich, 1980).

Three **patterns of distribution** of the coronary arteries have been described. In half the hearts, the right coronary predominates; in a third, the two vessels are equally balanced; and in the rest, the left coronary predominates. The *sinuatrial node* is supplied by a branch of the right coronary in 70%, by the left in 25%, by both in 7%. The *atrioventricular node* is supplied by the right in 92%. The *right atrioventricular bundle branch* generally is supplied by the anterior interventricular branch of the left coronary; the *left bundle branch* comes from septal branches of the left coronary artery and small vessels from the right coronary artery (Gregg, 1950).

### ARCH OF THE AORTA

The **arch of the aorta** (Figs. 8-14; 8-16) begins at the level of the upper border of the right second sternocostal articulation and runs at first upward, backward, and to the left, anterior to the trachea. It is then directed posteriorly on the left side of the trachea and finally curves downward to the left side of the body of the fourth thoracic vertebra, at the caudal border of which it becomes the descending aorta. It thus forms two curvatures: one with its convexity oriented superiorly, the other with its convexity directed anteriorly and to the left. The upper border of the aortic arch reaches superiorly

to about the middle of the manubrium, and the entire arch, which measures about 4.5 cm in length, is contained within the lower half of the superior mediastinum.

**RELATIONS.** *Anteriorly*, the arch of the aorta is covered by the pleura, the anterior margins of the lungs, and by the remains of the thymus. As the vessel courses posteriorly, its *left side* is in contact with the left lung and left mediastinal pleura. Additionally, to the left of the aortic arch are four nerves coursing downward in the thorax. In order, i.e., from front to back, these are the left phrenic, the inferior cervical cardiac branch of the left vagus, the superior cervical cardiac branch of the left sympathetic, and the trunk of the left vagus nerve. As the left vagus nerve crosses the arch, it gives off its recurrent branch, which hooks around the vessel and then passes superiorly on its right side. The left superior intercostal vein runs obliquely on the left side of the arch, between the phrenic and vagus nerves. On the *right side* of the aortic arch are the deep cardiac plexus, the right recurrent nerve, the esophagus, and the thoracic duct. The trachea lies posterior to and to the right of the vessel. *Superiorly* are the brachiocephalic, left common carotid, and left subclavian arteries, all of which arise from the convexity of the arch and are crossed close to their origins by the left brachiocephalic vein. *Inferiorly* are the bifurcation of the pulmonary trunk, the left principal bronchus, the ligamentum arteriosum, the superficial cardiac plexus, and the left recurrent nerve. As

stated above, the ligamentum arteriosum connects the pulmonary artery near its commencement to the aortic arch.

Between the origin of the left subclavian artery and the attachment of the ductus arteriosus, the lumen of the aorta in the fetus is considerably narrowed, forming what is termed the **aortic isthmus**, while immediately beyond the ductus arteriosus the vessel presents a fusiform dilation which has been called the **aortic spindle**. The point of junction of the two parts is marked in the concavity of the arch by an indentation or angle. This situation persists to some extent in the adult, in whom the average diameter of the spindle exceeds that of the isthmus by about 3 mm.

**VARIATIONS IN THE COURSE OF THE ARCH OF THE AORTA.** The height to which the aorta ascends in the thorax is usually about 2.5 cm below the cranial border of the sternum. This may vary, however, and the summit of the aorta may not ascend as high as this site, or it may rise as high as the upper border of the sternum. Sometimes the aorta arches over the root of the right lung (right aortic arch) instead of the left, passing along the right side of the vertebral column, a condition that is normal in birds. In such cases, the thoracic and abdominal viscera are usually transposed. Less frequently the aorta, after arching over the root of the right lung, passes dorsal to the esophagus to reach its usual position on the left side of the vertebral column. This variation is not accompanied by transposition of the viscera. As in some quadrupeds, the aorta occasionally divides into an ascending and a descending trunk. In these instances the ascending trunk is directed vertically upward and subdivides into three branches, which supply the head and upper limbs. Sometimes the aorta subdivides near its origin into two branches, which soon reunite. When this variation occurs, the esophagus and trachea are found to pass through the interval between the two branches. This is the normal condition of the vessel in the reptilian class of vertebrates.

**BRANCHES FROM THE ARCH OF THE AORTA.** Arising from the aortic arch are vessels that principally supply the neck, head, upper extremity, and, to some extent, the upper thoracic wall. In 83 to 94% of cadavers, there are three branches derived from the arch of the aorta: the **brachiocephalic trunk**, the **left common carotid artery**, and the **left subclavian artery** (Fig. 8-14). The latter two vessels will be discussed with the vasculature of the head, neck, and upper extremity. The brachiocephalic trunk will be described following a discussion of the possible variations in the branching pattern of these great vessels.

**VARIATIONS IN THE BRANCHING PATTERN OF THE ARCH OF THE AORTA.** The branches may arise from the commencement of the arch or upper part of the

ascending aorta, instead of from the highest part of the arch. The distance between the branches at their origins may be increased or diminished, the most frequent change in this respect being the approximation of the left common carotid artery toward the brachiocephalic trunk.

The number of the primary branches may be reduced to one, or more frequently two (7%), the left common carotid artery arising from the brachiocephalic trunk. More rarely, the common carotid and subclavian arteries of the left side arise from a left brachiocephalic artery. The number of branches from the aortic arch may be increased to four when the right common carotid and subclavian arteries arise directly from the aorta, the brachiocephalic trunk being absent. In most instances the right subclavian has been found to be the first branch and to arise from the left end of the arch, but in a few specimens it is the second or third branch from the arch. Another variation in which there are four primary branches from the aortic arch is that in which the left vertebral artery arises from the arch between the left common carotid and subclavian arteries. Finally the number of trunks from the arch may be increased to five or six, in which cases the external and internal carotid arteries arise separately from the arch, the common carotid being absent on one or both sides. In a few instances both vertebral arteries have been found to arise from the aortic arch.

When the aorta arches to the right side, the three branches have a reverse arrangement, with a brachiocephalic trunk coursing to the left and the right common carotid and subclavian arteries arising separately. In other instances, when the aorta takes its usual course to the left, the two carotids may arise as a common trunk, with the subclavian arteries originating separately from the arch and the right subclavian generally arising from the left end of the arch.

In some instances, other arteries branch from the arch of the aorta. Of these the most common are one or both of the **bronchial arteries** and the **thyroid ima artery**. Although rarely seen, it has been reported that the internal thoracic and inferior thyroid arteries may arise from the aortic arch.

### BRACHIOCEPHALIC TRUNK

The brachiocephalic trunk (formerly called the innominate artery) is the largest of the three branches arising from the arch of the aorta, and it measures 4 to 5 cm in length (Fig. 8-14). It arises near the commencement of the arch of the aorta, on a plane anterior to the origin of the left carotid. At its origin the brachiocephalic trunk is positioned behind the manubrium sterni at about the level of the upper border of the right second costal cartilage. The vessel courses superiorly, somewhat posteriorly, and obliquely to the

right to the level of the upper border of the right sternoclavicular articulation, where it divides into the **right common carotid** and **right subclavian arteries**.

**RELATIONS.** *Anteriorly*, the **brachiocephalic trunk** is separated from the manubrium sterni by the sternohyoid and sternothyroid muscles, the remains of the thymus, the left brachiocephalic and right inferior thyroid veins which cross its root, and sometimes the cardiac branches of the right vagus. *Posteriorly* lies the trachea, which the brachiocephalic trunk crosses obliquely. On the *right side* are the right brachiocephalic vein, the superior vena cava, the right phrenic nerve, and the pleura. On the *left side* are found the remains of the thymus, the origin of the left common carotid artery, the inferior thyroid veins, and more superiorly, the trachea.

The brachiocephalic trunk usually does not give off branches, but occasionally (in about 10% of cases) a small vessel, the **thyroid ima artery**, arises from it. At times a **thymic artery** or **bronchial artery** may arise from the brachiocephalic trunk.

**THYROID IMA ARTERY.** The thyroid ima artery, when present, ascends anterior to the trachea to the inferior part of the thyroid gland, which it supplies. It varies greatly in size and appears to compensate for a deficiency or absence of one of the other thyroid arteries. It occasionally arises from the aorta on the right common carotid, subclavian, or internal thoracic arteries.

**VARIATIONS.** The brachiocephalic trunk sometimes divides above the level of the sternoclavicular joint, less frequently below it. It may be absent, in which case the right subclavian and the right common carotid then arise directly from the aorta. When the aortic arch is on the right side, the brachiocephalic trunk is directed toward the left.

## Arteries of the Head and Neck

The principal arteries supplying the structures of the head and neck are the two **common carotids**. These vessels, one on each side, ascend in the neck, and at the level of the upper border of the thyroid cartilage (of the larynx) each divides into two branches. These branches are the **external carotid artery**, which supplies the exterior of the head, the face, and the greater part of the neck, and the **internal carotid artery**, which supplies to

a great extent the structures within the cranial and orbital cavities. The **vertebral arteries**, which branch from the subclavian arteries, also ascend in the neck and assist in supplying the brain. These will be described with the subclavian artery.

### COMMON CAROTID ARTERY

The **common carotid arteries** differ in length and in their mode of origin. The **right common carotid artery** begins at the bifurcation of the brachiocephalic trunk behind the right sternoclavicular joint and is confined to the neck. The **left common carotid artery** branches from the highest part of the arch of the aorta immediately to the left and slightly behind the brachiocephalic trunk. It therefore consists of a thoracic and a cervical portion.

The **thoracic portion of the left common carotid artery** is 2.5 to 3.5 cm in length and ascends from the arch of the aorta through the superior mediastinum to the level of the left sternoclavicular joint, where it becomes the cervical portion.

**RELATIONS.** *Anteriorly*, the thoracic portion of the left common carotid artery is separated from the manubrium sterni by the sternohyoid and sternothyroid muscles, the anterior portions of the left pleura and lung, the left brachiocephalic vein, and the remains of the thymus. *Posteriorly*, the vessel is related to the trachea, esophagus, left recurrent laryngeal nerve, and thoracic duct. To its *right side* are the brachiocephalic trunk, the trachea, the inferior thyroid veins, and the remains of the thymus. To its *left side* are the left vagus and phrenic nerves, left pleura, and lung. The left subclavian artery is posterior and slightly lateral to the left common carotid artery in the thorax.

The **cervical portions** of the two common carotid arteries resemble each other so closely that one description will apply to both. Each vessel passes obliquely from behind the sternoclavicular articulation, to the level of the upper border of the thyroid cartilage, where it divides into the external and internal carotid arteries (Figs. 8-19; 8-20; 8-24).

In the lower part of the neck the two common carotid arteries are separated by a narrow interval which contains the trachea. More superiorly in the neck, however, the thyroid gland, the larynx, and the pharynx

**Fig. 8-19.** The triangles of the neck. The sternocleidomastoid muscle separates the anterior from the posterior triangle. Observe the course of the carotid arteries in the neck.

project anteriorly between the two vessels. The common carotid artery is contained in the **carotid sheath**, which is derived from the deep cervical fascia. The sheath also encloses the internal jugular vein and vagus nerve, the vein lying lateral to the artery, and the nerve between the artery and vein on a plane posterior to both vessels. When the sheath is opened, each of the structures is seen to have a separate fibrous investment.

**RELATIONS.** In the *lower cervical region*, the common carotid artery lies quite deep, being covered by the integument, superficial fascia and platysma muscle, deep cervical fascia, and the sternocleidomastoid, sternohyoid, sternothyroid, and omohyoid muscles. *Above the superior belly of the omohyoid muscle*, the common carotid artery is more superficial, being covered only by the integument, the su-

perficial fascia and platysma, deep cervical fascia, and the medial margin of the sternocleidomastoid muscle (Fig. 8-19). When this muscle is drawn backward, the artery is seen in a triangular space, the **carotid triangle**, bounded posteriorly by the sternocleidomastoid, superiorly by the stylohyoid and posterior belly of the digastric, and inferiorly by the superior belly of the omohyoid muscle (Fig. 8-19). This part of the artery is crossed obliquely, from its medial to its lateral side, by the sternocleidomastoid branch of the superior thyroid artery; it is also crossed by the superior and middle thyroid veins which flow into the internal jugular. Usually superficial to the carotid sheath, but occasionally contained within it are the superior and inferior roots of the **ansa cervicalis**, which descend in the neck and form an interconnecting nerve loop from which the strap muscles of the neck are innervated (Fig. 8-20). The superior thyroid vein crosses the common carotid artery near its termination, and the middle thy-

**FIG. 8-20.** Superficial dissection of the right side of the neck showing the carotid and subclavian arteries and their branches. Note that the submandibular and parotid glands have been removed, as well as much of the sternocleidomastoid muscle and internal jugular veins in order to reveal the underlying arteries and nerves.

roid vein crosses the artery a little below the level of the cricoid cartilage. The anterior jugular vein crosses the artery just above the clavicle, but is separated from it by the sternohyoid and sternothyroid muscles. *Posteriorly*, the artery is separated from the transverse processes of the fourth, fifth, and sixth cervical vertebrae by the longus colli and longus capitis muscles, the sympathetic trunk being interposed between the common carotid and the muscles. The inferior thyroid artery crosses behind the lower part of the common carotid artery. *Medially*, the common carotid artery courses in relation to the esophagus, trachea, thyroid gland (which overlaps it), larynx, and pharynx, the inferior thyroid artery and recurrent laryngeal nerve being interposed. *Lateral* to the artery are the internal jugular vein and vagus nerve.

In the lower neck the right recurrent laryngeal nerve crosses obliquely dorsal to the artery. The right internal jugular vein diverges from the artery in the lower neck, but the left vein approaches and often overlaps it.

**CAROTID BODY.** The carotid body lies deep to the bifurcation of the common carotid artery or somewhat between the two branches. It is a small, flattened, oval structure, 2 to 5 mm in diameter, with a characteristic structure composed of epithelioid cells, which are in close relation to capillary sinusoids, and an abundance of nerve fibers. Surrounding the carotid body is a delicate fibrous capsule. It is part of the visceral afferent system of the body, containing chemoreceptor endings that respond to low levels of oxygen in the blood or high levels of carbon dioxide and lowered pH of the blood. It is supplied by nerve fibers from both the glossopharyngeal and vagus nerves.

**CAROTID SINUS.** The carotid sinus is a slight dilatation in the wall of the terminal portion of the common carotid artery and of the internal carotid artery at its origin. The

dilatation extends for about 1 cm in length and may be limited to the wall of the internal carotid artery only. The carotid sinus is an important organ for the regulation of systemic blood pressure. Special receptorlike nerve endings capable of responding to alterations in blood pressure are found in the arterial wall. The nerve fibers, which constitute the carotid branch of the glossopharyngeal nerve, transmit these impulses to the medulla oblongata of the brain stem. Cardiovascular reflex changes result from this homeostatic mechanism designed to return blood pressure to its more normal level by altering the rate of the heart beat.

**VARIATIONS.** The **right common carotid artery** arises above the level of the superior border of the sternoclavicular joint in about 12% of cadavers. This vessel may arise as a separate branch from the arch of the aorta, or in conjunction with the left common carotid. The **left common carotid artery** varies more frequently in its origin than the right. In the majority of abnormal specimens, it arises with the brachiocephalic trunk; if the latter vessel is absent, the two common carotids may arise as a single trunk. The site of division of the common carotid artery into its external and internal branches may vary. More frequently this occurs higher than normal (at about the level of the hyoid bone). More rarely division occurs more caudally, opposite the middle of the larynx or at the lower border of the cricoid cartilage. Very rarely, the common carotid ascends in the neck without dividing, and thus either the external or the internal carotid is absent. In a few instances the common carotid has been found to be absent, the external and internal carotids arising directly from the arch of the aorta.

The common carotid artery usually does not give off any branches before its bifurcation, but occasionally it does give origin to the superior thyroid or its laryngeal branch, the ascending pharyngeal, the inferior thyroid, or, more rarely, the vertebral artery.

**COLLATERAL CIRCULATION.** After ligation of one common carotid, collateral circulation can become perfectly established, owing to the free communication that exists between the carotid arteries of the two sides, both within the cranium and in the face and neck. Also there is enlargement of the branches of the subclavian artery on the side on which the common carotid artery has been tied. The chief communications outside the skull take place between the superior and inferior thyroid arteries, and between the deep cervical branch of the costocervical trunk and the descending branch of the occipital artery. Within the cranium, the vertebral artery supplies blood to the branches of the ligated internal carotid artery.

### **External Carotid Artery**

The **external carotid artery** (Fig. 8-20) begins opposite the upper border of the thyroid cartilage, and passing upward, it curves somewhat anteriorly and then inclines posteriorly to the space behind the neck of the mandible, where, in the substance of the parotid gland, it divides into the superficial temporal and maxillary arteries. It rapidly diminishes in size in its course up the neck, owing to the number and large size of its branches. In the child, it is somewhat smaller than the internal carotid, but in the adult, the two vessels are of nearly equal size. At its origin, the external carotid is more superficial and nearer the midline than the internal carotid, and is contained within the carotid triangle.

**RELATIONS.** Within the carotid triangle, the **external carotid artery** lies deep to the skin, superficial fascia, platysma, deep fascia, and anterior margin of the sternocleidomastoid muscle. It is crossed by the hypoglossal nerve and its vena comitans and by the lingual, facial, and superior thyroid veins. Just above the carotid triangle it lies deep to the posterior belly of the digastric and stylohyoid muscles. More superiorly, it penetrates into the substance of the parotid gland, where it lies deep to the facial nerve and the junction of the superficial temporal and maxillary veins. Medial (or deep) to the artery are found initially the hyoid bone, the wall of the pharynx, and the superior laryngeal nerve. More superiorly it is separated from the internal carotid artery by the styloglossus and stylopharyngeus muscles, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve, and part of the parotid gland.

### **Branches of the External Carotid Artery**

Eight branches arise from the external carotid artery, usually in the following order:

- Superior thyroid
- Ascending pharyngeal
- Lingual
- Facial
- Occipital
- Posterior auricular
- Superficial temporal
- Maxillary

**SUPERIOR THYROID ARTERY**

The **superior thyroid artery** (Figs. 8-20; 8-21; 8-24) arises from the anterior aspect of the external carotid artery just caudal to the level of the greater horn of the hyoid bone and ends in the thyroid gland. In 16% of cadavers the superior thyroid artery arises from the common carotid artery. From its origin deep to the anterior border of the sternocleidomastoid muscle, it initially courses upward and forward for a short distance in the carotid triangle, where it is covered by the skin, platysma, and fascia. The superior thyroid artery then arches downward deep to the omohyoid, sternohyoid, and sternothyroid muscles. To its medial side are the inferior pharyngeal constrictor muscle and the external branch of the superior laryngeal nerve.

**Branches of the  
Superior Thyroid Artery**

The superior thyroid artery distributes small vessels to adjacent muscles, and usually two main branches to the thyroid gland. One of these, the **anterior branch**, is larger and supplies principally the ventral surface of the gland. At the isthmus of the thyroid gland, the anterior branch anastomoses with the corresponding artery of the opposite side. Also coursing to the thyroid gland is the **posterior branch**, which descends on the dorsal surface of the gland and anastomoses with the inferior thyroid artery.

In addition to the glandular branches and small muscular twigs, the branches of the superior thyroid are:

- Infrahyoid
- Sternocleidomastoid
- Superior laryngeal
- Cricothyroid

**INFRAHYOID BRANCH.** The infrahyoid branch of the superior thyroid artery is small and runs along the lower border of the hyoid bone (Fig. 8-20). It lies on the thyrohyoid membrane, deep to the thyrohyoid muscle, and anastomoses with the suprahyoid branch of the lingual artery and with the infrahyoid branch of the opposite side.

**STERNOCLEIDOMASTOID BRANCH.** The sternocleidomastoid branch of the superior thyroid artery courses downward and laterally across the carotid sheath and supplies the

middle part of the sternocleidomastoid muscle and neighboring muscles and integument (Fig. 8-24). It frequently arises as a separate branch from the external carotid artery.

**SUPERIOR LARYNGEAL ARTERY.** The superior laryngeal artery, larger than either of the preceding, passes medially and accompanies the internal laryngeal branch of the superior laryngeal nerve, deep to the thyrohyoid muscle (Fig. 8-21). It pierces the thyrohyoid membrane and supplies the muscles, mucous membrane, and glands of the larynx, anastomosing the inferior laryngeal branch of the inferior thyroid artery with the superior laryngeal artery from the opposite side. It sometimes (13%) arises separately from the external carotid.

**CRICOTHYROID BRANCH.** The cricothyroid branch of the superior laryngeal artery is small and runs transversely across the cricothyroid membrane, anastomosing with the artery of the opposite side (Figs. 8-20; 8-24).

**ASCENDING PHARYNGEAL ARTERY**

The ascending pharyngeal artery (Figs. 8-20; 8-23; 8-24) is the smallest branch of the external carotid artery. Being a long, slender vessel, it is deeply placed in the neck, dorsal to the other branches of the external carotid and to the stylopharyngeus. It arises from the posterior part of the external carotid artery, near the origin of that vessel, and ascends vertically to the inferior surface of the base of the skull, between the internal carotid and the side of the pharynx, anterior to the longus capitis muscle. In 14% of cadavers it arises from the occipital artery, and occasionally it may arise from the internal carotid artery.

**Branches of the  
Ascending Pharyngeal Artery**

The branches of this vessel are small and somewhat variable. In its ascent, it helps to supply the pharynx, the soft palate, the rectus capitis and longus capitis muscles, the superior cervical ganglion, the medial wall of the tympanic cavity, and the dura mater covering the brain. It anastomoses with the ascending palatine branch of the facial artery. Its branches are:

- Pharyngeal
- Palatine

Prevertebral  
Inferior tympanic  
Meningeal

**PHARYNGEAL BRANCHES.** Three or four pharyngeal branches arise from the ascending pharyngeal artery. These supply the superior and middle constrictor muscles, as well as the mucous membrane lining the pharynx. One branch supplies the stylopharyngeus muscles. These branches anastomose with vessels from the superior thyroid artery.

**PALATINE BRANCH.** The palatine branch (which is considered by some authors as one of the pharyngeal branches) may take the place of the ascending palatine branch of the facial artery, when that vessel is small. It passes beyond the upper border of the superior constrictor muscle and sends ramifications to the soft palate and tonsil, supplying also a branch to the auditory tube.

**PREVERTEBRAL BRANCHES.** These are numerous small vessels that supply the longus capitis and longus colli muscles, the sympathetic trunk, the hypoglossal and vagus nerves, and a number of the deep cervical lymph nodes. These small arteries anastomose with the ascending cervical branch of the inferior thyroid artery.

**INFERIOR TYMPANIC ARTERY.** The inferior tympanic artery is a small vessel that passes, with the tympanic branch of the glossopharyngeal nerve, through a minute foramen, the tympanic canaliculus, in the petrous portion of the temporal bone. Entering the middle ear, it supplies the medial wall of the tympanic cavity and anastomoses with the other tympanic arteries.

**MENINGEAL BRANCHES.** Several small meningeal vessels branch from the ascending pharyngeal artery to supply the dura mater. One, the **posterior meningeal artery**, enters the cranium through the jugular foramen; a second passes through the foramen lacerum; and occasionally a third passes through the canal for the hypoglossal nerve.

## LINGUAL ARTERY

The lingual artery (Figs. 8-20; 8-24) arises from the external carotid between the superior thyroid and facial arteries, opposite the tip of the greater horn of the hyoid bone. Supplying structures in the floor of the oral

cavity, it is the principal artery to the tongue. Initially it courses obliquely upward and medially above the greater horn of the hyoid bone. It then curves downward and anteriorly to form a loop, which is crossed by the hypoglossal nerve. Coursing deep to the posterior belly of the digastric and stylohyoid muscles, the lingual artery then runs horizontally under cover of (i.e., medial to) the hyoglossus muscle to ascend perpendicularly to the tongue. The artery then turns anteriorly as the **deep lingual artery** and courses along the inferior surface of the tongue as far as the tip.

Frequently, the lingual and facial arteries arise as a common vessel, the **linguofacial trunk**, from the external carotid artery. The trunk courses a short distance superomedially before dividing into the lingual and facial arteries.

**RELATIONS.** The *first (or oblique) part* of the **lingual artery** lies superficially and is contained within the carotid triangle. It rests on the middle pharyngeal constrictor muscle and is covered by the skin, platysma, and fascia of the neck. Its *second (or curved) part* also rests on the middle pharyngeal constrictor, being covered at first by the tendon of the digastric muscle and by the stylohyoid muscle, and more anteriorly by the hyoglossus. Its *third (or horizontal) part* lies between the hyoglossus and genioglossus. The *fourth (or terminal) part* of the vessel, called the **deep lingual artery (ranine artery)**, runs along the inferior surface of the tongue to its tip. At this site it is quite superficial, being covered only by the mucous membrane. Deep to the artery are the inferior longitudinal muscle of the tongue and, on its medial side, the genioglossus muscle. The **hypoglossal nerve** crosses the first part of the lingual artery, but is separated from the second part by the hyoglossus muscle.

## Branches of the Lingual Artery

Four named branches of the lingual artery are usually identified. They are:

Suprahyoid  
Dorsal lingual  
Sublingual  
Deep lingual

**SUPRAHYOID BRANCH.** The suprahyoid branch of the lingual artery is quite small and courses along the superior border of the hyoid bone, supplying some of the muscles attached to it (Fig. 8-21). The vessel anasto-

moses with the infrahyoid branch of the superior thyroid artery and with the suprahyoid branch of the opposite side.

**DORSAL LINGUAL BRANCHES.** There are usually two or three small dorsal lingual branches of the lingual artery, and they arise medial to and under cover of the hyoglossus muscle (Fig. 8-24). They ascend to the posterior part of the dorsum of the tongue and supply the mucous membrane of this region, the palatoglossal arch, the tonsil, soft palate, and epiglottis. There is some anastomosis with tonsillar arteries and with vessels of the opposite side.

**SUBLINGUAL ARTERY.** The sublingual artery arises at the anterior margin of the hyoglossus muscle and courses anteriorly between the genioglossus and mylohyoid muscles to achieve the sublingual gland. It supplies the gland and gives branches to the

mylohyoid and neighboring muscles and to the mucous membrane of the mouth and gums. Small vessels supply the sides of the tongue, and the artery to the frenulum of the tongue is usually derived from the sublingual artery. One branch, running medial to the alveolar process of the mandible in the substance of the gum, anastomoses with a similar artery from the other side; another pierces the mylohyoid muscle and anastomoses with the submental branch of the facial artery.

**DEEP LINGUAL ARTERY.** The deep lingual artery (also known as the ranine artery) is the terminal portion of the lingual artery; it pursues a tortuous course, running along the inferior lingual surface, between the inferior longitudinal muscle of the tongue and the mucous membrane (Fig. 8-24). Lying on the lateral side of the genioglossus muscle, it is

**FIG. 8-21.** The arteries of the face and scalp viewed from the right side. Both the submandibular and parotid glands have been removed to reveal the course of the external carotid artery behind the ramus of the mandible. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 1975.)

accompanied by the lingual vein and the terminal part of the lingual nerve. It anastomoses with the artery of the opposite side at the tip of the tongue.

#### **FACIAL ARTERY**

The facial artery (Figs. 8-20; 8-21; 8-23) arises in the carotid triangle a little superior to the lingual artery and, sheltered by the ramus of the mandible, passes obliquely deep to the posterior belly of the digastric and the stylohyoid muscles. It then arches anteriorly to enter a groove on the posterior surface of the submandibular gland where it joins the facial vein. Becoming quite superficial, the facial artery winds around the inferior border of the mandible at the anterior edge of the masseter muscle to enter the face. It crosses the cheek lateral to the angle of the mouth and, as the **angular artery**, ascends along the side of the nose, to end at the medial palpebral commissure of the eye. At this site it anastomoses with the dorsal nasal branch of the ophthalmic artery. The facial artery, both in the neck and on the face, is remarkably tortuous. In the neck, this may assist the vessel to accommodate itself to movements of the pharynx in deglutition, and in the face, to movements of the mandible, lips, and cheeks.

**RELATIONS.** *In the neck*, the origin of the facial artery is quite superficial, being covered by the integument, platysma, and fascia. It then passes deep to the posterior belly of the digastric and the stylohyoid muscle, part of the submandibular gland, and frequently the hypoglossal nerve. It lies on the medial and superior pharyngeal constrictor muscles, the latter separating the vessel at the summit of its arch from the tonsil. *On the face*, where the facial artery passes over the body of the mandible, it is also superficial, lying immediately beneath the platysma. In its course over the face, it is covered by the integument, the fat of the cheek, and near the angle of mouth, by the platysma, risorius, and zygomaticus major muscles. It rests on the buccinator and levator anguli oris, and passes either superficial or deep to the levator labii superioris. The anterior facial vein lies lateral to the artery and takes a more direct course across the face. Branches of the facial nerve cross the artery.

#### **Branches of the Facial Artery**

The branches of the facial artery may be divided into two sets: those given off in the neck, **cervical**, and those on the face, **facial**.

Cervical Branches  
  Ascending palatine  
  Tonsillar  
  Glandular  
  Submental  
Facial Branches  
  Inferior labial  
  Superior labial  
  Lateral nasal  
  Angular

Additionally, *muscular branches* are given off both in the neck and in the face.

**ASCENDING PALATINE ARTERY.** The ascending palatine artery (Figs. 8-21; 8-23) arises close to the origin of the facial artery and passes upward between the styloglossus and stylopharyngeus muscles to the side of the pharynx, along which it continues between the superior pharyngeal constrictor and the medial pterygoid muscles toward the base of the skull. It divides near the levator veli palatini muscle into two branches. One branch follows the course of this muscle, and, winding over the upper border of the superior pharyngeal constrictor, supplies the soft palate and the palatine glands, anastomosing with its fellow of the opposite side and with the greater palatine branch of the maxillary artery. The other branch pierces the superior pharyngeal constrictor muscle and supplies the palatine tonsil and auditory tube, anastomosing with the tonsillar branch of the facial artery and the ascending pharyngeal branch of the external carotid artery.

**TONSILLAR BRANCH.** The tonsillar branch of the facial artery (Fig. 8-24) ascends between the medial pterygoid and styloglossus muscles. On the side of the pharynx, at the level of the palatine tonsil, it perforates the superior pharyngeal constrictor to ramify in the substance of the palatine tonsil and root of the tongue. Penetrating the lower pole of the tonsillar bed, this vessel is usually the primary arterial supply to the tonsil.

**GLANDULAR BRANCHES.** As the facial artery courses near the submandibular gland, three or four large branches are distributed to the submandibular gland, some being prolonged to the neighboring muscles, lymph nodes, and integument. Generally, a small branch supplies the submandibular duct (of Wharton<sup>1</sup>).

<sup>1</sup>Thomas Wharton (1610-1673): An English anatomist (London).

**SUBMENTAL ARTERY.** The submental artery, being the largest of the cervical branches, comes off the facial artery just as that vessel emerges from beneath the submandibular gland (Figs. 8-20; 8-21). It runs anteriorly upon the mylohyoid muscle just below the body of the mandible and deep to the anterior belly of the digastric. It supplies the surrounding muscles and anastomoses with the sublingual branch of the lingual artery and with the mylohyoid branch of the inferior alveolar artery. At the symphysis menti, the submental artery turns upward over the border of the mandible and divides into a superficial and a deep branch. The *superficial branch* passes between the skin and the levator labii inferioris muscle, and anastomoses with the inferior labial artery. The *deep branch* runs between this same muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

**INFERIOR LABIAL ARTERY.** The inferior labial artery arises near the angle of the mouth (Figs. 8-22; 8-23). It passes anteriorly beneath the depressor anguli oris and, penetrating the orbicularis oris, runs a tortuous course along the edge of the lower lip, between this muscle and the mucous membrane. It supplies the labial glands, the mucous membrane, and the muscles of the lower lip. The inferior labial artery anastomoses with the same vessel of the opposite side and with the mental branch of the inferior alveolar artery.

**SUPERIOR LABIAL ARTERY.** The superior labial artery is larger and more tortuous than the inferior (Figs. 8-22; 8-23). It follows a comparable course along the edge of the upper lip, passing deep to the zygomaticus major muscle to lie between the mucous membrane and the orbicularis oris. It sup-

plies the upper lip and anastomoses with the artery of the opposite side. Additionally, the superior labial artery sends at least two branches that ascend to the nose. These are the **septal branch**, which ramifies on the nasal septum as far as the point of the nose, and the **alar branch**, which supplies the ala of the nose.

**LATERAL NASAL BRANCH.** The lateral nasal branch of the facial artery is derived from the larger trunk as that vessel ascends alongside the nose. It supplies the ala and dorsum of the nose, anastomosing with its fellow from the other side, with the septal and alar branches of the superior labial artery, with the dorsal nasal branch of the ophthalmic artery, and with the infraorbital branch of the maxillary artery.

**ANGULAR ARTERY.** The angular artery (Figs. 8-21; 8-23) is actually the terminal part of the facial. It ascends in the groove lateral to the nose to the medial angle of the orbit, embedded in the fibers of the levator labii superioris alaeque nasi and is accompanied by the angular vein. The branches of the angular artery anastomose with the infraorbital artery, and after supplying the lacrimal sac and orbicularis oculi muscle, it ends by anastomosing with the dorsal nasal branch of the ophthalmic artery.

**MUSCULAR BRANCHES.** Unnamed separate muscular arteries frequently branch directly from the main trunk of the facial artery. From the cervical part of the vessel a branch generally ascends to the medial pterygoid muscle in the face and another supplies the stylohyoid muscle. Muscular branches arising from the artery on the face supply the masseter and buccinator muscles as well as the muscles of expression.

**Fig. 8-22.** The labial arteries, the glands of the lips, and the nerves of the right side seen from the inner surface of the oral cavity after removal of the mucous membrane. (From Poirier and Charpy.)

**ANASTOMOSES OF THE FACIAL ARTERY.** The anastomoses of the facial artery are quite numerous, not only across the midline with branches of the same vessel of the opposite side, but in the neck, with the sublingual branch of the lingual, with the ascending pharyngeal, and by its ascending palatine and tonsillar branches with the greater palatine branch of the maxillary. On the face, branches of the facial artery anastomose with the mental branch of the inferior alveolar artery as it emerges from the mental foramen, with the transverse facial branch of the superficial temporal artery, with the infraorbital branch of the maxillary artery, and with the dorsal nasal branch of the ophthalmic artery.

**VARIATIONS.** The facial and lingual arteries frequently arise as a common vessel, the **linguofacial trunk**, which quickly divides into separate facial and lingual branches. The facial artery may vary in size and in the extent to which it supplies the face. It occasionally ends by forming the submental artery at the level of the chin, and not infrequently extends only as high as the angle of the mouth or nose. The deficiency is then compensated for by an enlargement of the neighboring arteries.

## OCCIPITAL ARTERY

The occipital artery arises from the posterior part of the external carotid artery, opposite the origin of the facial artery near the lower margin of the posterior belly of the digastric muscle (Figs. 8-20; 8-21; 8-23). It is generally a vessel of considerable size and ends in the posterior part of the scalp.

**COURSE AND RELATIONS.** At its origin, the **occipital artery** is covered by the posterior belly of the digastric and the stylohyoid muscles. It is crossed by the hypoglossal nerve as that nerve winds around the vessel in its course toward the tongue. The vessel crosses the internal carotid artery, the internal jugular vein, and the vagus and accessory nerves. The artery next ascends to the interval between the transverse process of the atlas and the mastoid process of the temporal bone, passing backward and upward along the occipital groove of the latter bone. In its course, the occipital artery is covered by the sternocleidomastoid, splenius capitis, and longissimus capitis muscles, and the posterior belly of the digastric muscle, and rests sequentially on the rectus capitis lateralis, the obliquus capitis superior, and the semispinalis capitis muscles. Posteriorly at the base of the skull, the artery changes its course and runs vertically upward, piercing the fascia connecting the cranial attachments of the trapezius and

sternocleidomastoid muscles. The occipital artery then ascends in a tortuous course within the superficial fascia of the scalp, where it divides into numerous branches. These branches reach as high as the vertex of the skull, anastomosing with the posterior auricular and superficial temporal arteries. The terminal portion of the occipital artery is accompanied by the greater occipital nerve.

## Branches of the Occipital Artery

Arising from the occipital artery are the following branches:

- Muscular
- Sternocleidomastoid
- Auricular
- Mastoid
- Meningeal
- Descending
- Terminal (Occipital)

**MUSCULAR BRANCHES.** Unnamed muscular branches of the occipital artery supply the digastric, stylohyoid, splenius, and longissimus capitis muscles.

**STERNOCLEIDOMASTOID ARTERY.** The sternocleidomastoid artery generally arises from the occipital artery close to its origin, but sometimes springs directly from the external carotid (Fig. 8-23). It passes downward and backward over the hypoglossal nerve and enters the substance of the muscle, in company with the accessory nerve. This artery anastomoses with the sternocleidomastoid branch of the superior thyroid artery. Frequently two sternocleidomastoid vessels arise from the occipital artery.

**AURICULAR BRANCH.** The auricular branch of the occipital artery ascends over the mastoid process of the temporal bone to supply the back of the cartilaginous concha of the external ear. It sometimes replaces the posterior auricular artery.

**MASTOID BRANCH.** The mastoid branch arises either from the occipital artery or from its auricular branch. It is a small vessel that enters the skull through the mastoid foramen and supplies the diploë, the dura mater, and the mastoid air cells. It anastomoses with the middle meningeal artery.

**MENINGEAL BRANCHES.** One or more long, slender meningeal branches arise from the occipital artery and ascend, with the internal jugular vein, to enter the cranial cavity through the jugular foramen and condyloid

canal. They supply the dura mater lining the posterior fossa of the skull.

**DESCENDING BRANCH.** The descending branch is the largest of the vessels arising from the occipital artery (Fig. 8-24). It courses downward in the posterior neck and divides into a superficial and a deep branch. The **superficial branch** lies deep to the splenius, giving off branches which pierce that muscle to supply the trapezius and anastomose with the superficial branch of the transverse cervical. The **deep branch** descends between the semispinales capitis and cervicis and anastomoses with the vertebral artery and with the deep cervical artery, a branch of the costocervical trunk. The anastomoses among these vessels assist in establishing a collateral circulation after ligation of the common carotid or subclavian artery.

**TERMINAL (OR OCCIPITAL) BRANCHES.** The terminal (or occipital) branches of the occipital artery are distributed to the scalp on the back of the head. They are very tortuous and lie between the skin and the occipital belly of the occipitofrontalis muscle. Anastomosing with similar vessels from the opposite side and with the posterior auricular and superficial temporal arteries, these terminal branches of the occipital artery supply the occipital belly of the occipitofrontalis muscle, the skin, and the pericranium. One of the terminal branches may give off a meningeal twig, which passes through the parietal foramen to help supply the dura mater.

#### POSTERIOR AURICULAR ARTERY

The posterior auricular artery is small and arises from the external carotid just above the posterior belly of the digastric and stylohyoid muscles opposite the apex of the styloid process (Figs. 8-20; 8-21; 8-23). The vessel ascends on the styloid process of the temporal bone under cover of the parotid gland to the groove between the cartilage of the external ear and the mastoid process, where it divides into its auricular and occipital branches.

#### Branches of the Posterior Auricular Artery

In addition to several small branches that the posterior auricular artery supplies to the digastric, stylohyoid, and sternocleidomas-

toid muscles and to the parotid gland, this vessel gives off three branches:

Stylomastoid  
Auricular  
Occipital

**STYLOMASTOID ARTERY.** The stylomastoid artery enters the stylomastoid foramen and supplies the mucous membrane of the tympanic cavity, the mastoid antrum and mastoid cells, and the semicircular canals (Fig. 8-23). In young subjects, a branch from this vessel, the **posterior tympanic artery** (along with the anterior tympanic artery from the maxillary), forms a vascular ring that surrounds the inner surface of the tympanic membrane and sends delicate vessels to ramify on that membrane. The stylomastoid artery anastomoses with the petrosal branch of the middle meningeal artery by a twig, which enters the hiatus of the facial canal.

**AURICULAR BRANCH.** The auricular branch of the posterior auricular artery ascends behind the ear, deep to the auricularis posterior, and is distributed to the back of the auricle, upon which it ramifies minutely. Some branches curve around the margin of the cartilage, while others perforate it to supply the anterior surface. The auricular branch of the posterior auricular artery anastomoses with the parietal and anterior auricular branches of the superficial temporal artery.

**OCCIPITAL BRANCH.** The occipital branch passes posteriorly over the sternocleidomastoid muscle to the scalp above and behind the ear. It supplies the occipital belly of the occipitofrontalis muscle and the other layers of the scalp in this region, and it anastomoses with the occipital artery (Figs. 8-21; 8-23).

#### SUPERFICIAL TEMPORAL ARTERY

The superficial temporal artery is the smaller of the two terminal branches of the external carotid and appears to be the continuation of that vessel (Figs. 8-20; 8-21; 8-23). It begins in the substance of the parotid gland posterior to the neck of the mandible and crosses over the posterior root of the zygomatic process of the temporal bone. About 5 cm above this process, the superficial temporal artery divides into its frontal and parietal branches.

**RELATIONS.** As it crosses the zygomatic process, the superficial temporal artery is covered by the auricularis anterior muscle and by a dense fascia. Within the substance of the parotid gland, the artery is crossed by the temporal and zygomatic branches of the facial nerve and one or two veins. In its course along the side of the head, it is accompanied by the auriculotemporal nerve, which lies immediately posterior to it. Just above the zygomatic process and in front of the auricle, the superficial temporal artery is quite superficial, being covered only by skin and fascia, and can easily be felt pulsating. This artery is often used for determining the pulse, particularly by anesthesiologists.

#### Branches of the Superficial Temporal Artery

Besides some twigs to the parotid gland, the temporomandibular joint, and the masseter muscle, the superficial temporal artery gives rise to the following branches:

- Transverse facial
- Middle temporal
- Zygomatico-orbital
- Anterior auricular
- Frontal
- Parietal

**TRANSVERSE FACIAL ARTERY.** The transverse facial artery is the largest branch of the superficial temporal artery and is given off even before the superficial temporal artery emerges from the substance of the parotid gland (Figs. 8-20; 8-21). Initially the transverse facial artery is deeply placed in the parotid gland, and coursing anteriorly, the vessel then passes transversely across the side of the face, between the parotid duct and the inferior border of the zygomatic arch. It divides into numerous branches, which supply the parotid gland and duct, the masseter muscle, and the skin. Branches of the transverse facial artery anastomose with the facial, masseteric, buccal, and infraorbital arteries. This vessel rests on the masseter muscle and is accompanied by one or two branches of the facial nerve.

**MIDDLE TEMPORAL ARTERY.** The middle temporal artery arises immediately above the zygomatic arch and, perforating the temporal fascia, lies against the squama of the temporal bone, where it sends branches to the temporalis muscle (Fig. 8-23). This vessel anastomoses with the deep temporal branches of the maxillary artery.

**ZYGOMATICO-ORBITAL ARTERY.** The zygomatico-orbital artery courses between the two layers of temporal fascia along the superior border of the zygomatic arch to the lateral angle of the orbit (Fig. 8-21). This vessel supplies the orbicularis oculi muscle and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery. It may arise from the middle temporal artery instead of branching directly from the superficial temporal artery.

**ANTERIOR AURICULAR BRANCHES.** Three or four anterior auricular branches are distributed to the anterior portion of the auricle, the tragus, the lobule, and part of the external acoustic meatus. They anastomose with the posterior auricular artery.

**FRONTAL BRANCH.** The frontal branch of the superficial temporal artery takes a tortuous course anteriorly and upward toward the forehead, supplying the muscles, integument, and pericranium in this region (Figs. 8-21; 8-23). It anastomoses with the supraorbital and supratrochlear branches of the ophthalmic artery.

**PARIETAL BRANCH.** The parietal branch is larger than the frontal, curves upward and backward on the side of the head, and lies between the skin and the temporal fascia (Figs. 8-21; 8-23). It anastomoses anteriorly with the frontal branch of the superficial temporal artery, posteriorly with the posterior auricular and occipital branches of the external carotid, and across the vertex of the skull with the parietal branch of the other side.

#### MAXILLARY ARTERY

The maxillary artery is the larger of the two terminal branches of the external carotid (Figs. 8-20; 8-23). It arises behind the neck of the mandible and is at first embedded in the substance of the parotid gland. It passes anteriorly between the ramus of the mandible and the sphenomandibular ligament, and then courses to the pterygopalatine fossa, either superficial or deep to the lateral pterygoid muscle. It supplies the deep structures of the face and may be divided into **mandibular**, **pterygoid**, and **pterygopalatine portions**.

The first or **mandibular portion** lies between the neck of the mandible and the sphenomandibular ligament, courses hori-

zontally forward, nearly parallel to but a little below the auriculotemporal nerve. It is embedded in the parotid gland and crosses the inferior alveolar nerve while running along the inferior border of the lateral pterygoid muscle.

The **second or pterygoid portion** arches forward and upward under cover of the ramus of the mandible and the insertion of the temporalis muscle. It lies either superficial or deep to the lower head of the lateral pterygoid muscle. When it lies superficial to the latter muscle, the vessel is located between the lateral pterygoid and temporalis muscles. When the vessel lies more deeply, it is located between the lateral pterygoid muscle and branches of the mandibular nerve, lying close to the lateral pterygoid plate. In this latter situation, the artery then penetrates the muscle to gain entrance to the pterygopalatine fossa. This portion supplies the muscles of mastication and the buccinator.

The **third or pterygopalatine portion** is a short segment of the maxillary artery, lying in the pterygopalatine fossa. It gives off several important branches and makes its way toward the sphenopalatine foramen, passing beside the pterygopalatine ganglion and terminating as the sphenopalatine artery. The course of the third part of the maxillary artery is the same in both superficially and deeply running vessels. It sends branches to the orbit and anterior face, the paranasal sinuses, nasal cavity and nasopharynx, and the upper teeth and palate.

The origin of branches of the first two parts of the maxillary artery differs somewhat, depending on whether the vessel courses superficial or deep to the lateral pterygoid muscle.

#### Branches of the First (or Mandibular) Portion of the Maxillary Artery

The descriptions of the following branches pertain to those instances in which the maxillary artery takes a more superficial course in the deep face:

- Deep auricular
- Anterior tympanic
- Inferior alveolar
- Middle meningeal
- Accessory meningeal

**DEEP AURICULAR ARTERY.** The deep auricular is a small vessel that ascends in the substance of the parotid gland, deep to the temporomandibular articulation (Fig. 8-23). It pierces the cartilaginous or bony wall of the external acoustic meatus and supplies its cuticular lining and the outer surface of the tympanic membrane. It gives a branch to the temporomandibular joint as it courses behind the articular capsule.

**ANTERIOR TYMPANIC ARTERY.** The anterior tympanic artery is small and often arises in common with the deep auricular artery (Fig. 8-23). It passes behind the temporomandibular articulation and enters the tympanic cavity through the petrotympanic fissure. Within the middle ear it ramifies upon the inner surface of the tympanic membrane, forming a vascular circle around the membrane with the stylomastoid branch of the posterior auricular artery. The anterior tympanic artery also anastomoses with the artery of the pterygoid canal and with the caroticotympanic branch from the internal carotid artery.

**INFERIOR ALVEOLAR ARTERY.** The inferior alveolar artery arises from the maxillary artery as that vessel courses between the neck of the mandible and the sphenomandibular ligament. It then descends with the inferior alveolar nerve to the mandibular foramen on the medial surface of the ramus of the mandible (Fig. 8-23). The artery then enters the mandibular canal with the nerve and courses through the canal to the first premolar tooth, where it divides into the mental and incisor branches. Along its course, the inferior alveolar artery also gives off mylohyoid and dental branches and a small lingual branch.

The **mylohyoid artery** arises from the inferior alveolar artery just before the latter vessel enters the mandibular foramen. It runs in the mylohyoid groove on the medial surface of the mandibular ramus, along with the mylohyoid nerve, to the inferior surface of the mylohyoid muscle, which it supplies.

The **incisor branch**, which is one of the terminal branches of the inferior alveolar artery, continues in the mandibular canal to the midline anteriorly, where it gives branches to the incisor teeth and anastomoses with a similar vessel from the opposite side.

The **mental branch**, which is the other terminal branch of the inferior alveolar artery,

**Fig. 8-23.** The right maxillary artery exposed in the infratemporal and pterygopalatine regions by the removal of the parotid gland, ramus of mandible, zygomatic arch, and muscles of mastication. Note the facial, occipital, ascending pharyngeal, posterior auricular, and superficial temporal branches of the right external carotid artery. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, 1975.)

emerges with the mental nerve from the mental foramen to supply the chin (Fig. 8-23). It anastomoses with the submental and inferior labial branches of the facial artery.

The **dental branches** of the inferior alveolar artery correspond in number to the roots of the lower teeth. They enter the minute apertures at the extremities of the roots and supply the pulp of the teeth.

The **lingual branch**, which is small, arises from the inferior alveolar artery near its origin and descends with the lingual nerve to supply the mucous membrane of the mouth.

**MIDDLE MENINGEAL ARTERY.** The middle meningeal artery is the largest of the arteries that supply the dura mater (Fig. 8-23). It ascends between the sphenomandibular ligament and the lateral pterygoid muscle and between the two roots of the auriculotemporal nerve to the *foramen spinosum* of the sphenoid bone, through which it enters the cranial cavity accompanied by two small veins and some sympathetic nerve fibers.

Finally, in a groove on the great wing of the sphenoid bone that extends to the squamous part of the temporal bone, the middle meningeal artery divides into frontal (or anterior) and parietal (or posterior) branches.

The **frontal (or anterior)** branch is the larger of the two principal terminal branches. It crosses the great wing of the sphenoid to reach the groove, or canal, in the sphenoidal angle of the parietal bone. It then divides into branches that spread out between the dura mater and internal surface of the cranium, some passing upward as far as the vertex, and others backward to the occipital region.

The **parietal (or posterior)** branch curves backward on the squamous part of the temporal bone, and reaching the parietal bone some distance anterior to its mastoid angle, it divides into branches that supply the posterior part of the dura mater and cranium. The branches of the middle meningeal artery are distributed partly to the dura mater,

but chiefly to the bones. They anastomose with the arteries of the opposite side and with the anterior meningeal (from the anterior ethmoid) and posterior meningeal (from the vertebral) arteries.

The middle meningeal artery, as it enters the cranium, gives off several other branches. A number of small **ganglionic vessels** supply the trigeminal ganglion, the roots of the trigeminal nerve, and the dura mater nearby. A **petrosal branch**, which enters the hiatus for the greater petrosal nerve, supplies the facial nerve and anastomoses with the stylomastoid branch of the posterior auricular artery. A **superior tympanic artery** runs in the canal for the tensor tympani and supplies this muscle and the lining membrane of the canal. An **anastomotic branch with the lacrimal artery** passes through the superior orbital fissure or through separate canals in the great wing of the sphenoid bone to achieve the orbit. It anastomoses with the recurrent meningeal branch of the lacrimal artery. Occasionally, the lacrimal artery may arise from the middle meningeal artery. **Temporal branches** pass through small foramina in the great wing of the sphenoid and anastomose in the temporal fossa with the deep temporal arteries.

**ACCESSORY MENINGEAL ARTERY.** The accessory meningeal artery may arise directly from the maxillary artery or, by means of a common vessel, with the middle meningeal artery. It enters the cranial cavity by passing upward along the course of the mandibular division of the trigeminal nerve through the foramen ovale. The accessory meningeal artery supplies muscles in its upward course in the deep face and, within the cranial cavity, supplies the trigeminal ganglion and dura mater.

#### Branches of the Second (or Pterygoid) Portion of the Maxillary Artery

The descriptions of the following branches pertain to those instances in which the maxillary artery takes a more superficial course in the deep face. The branches of this second portion supply muscles.

Deep temporal  
Pterygoid

Masseteric  
Buccal

**DEEP TEMPORAL BRANCHES.** There are generally two deep temporal branches, an **anterior** and a **posterior** (Fig. 8-23). These ascend between the temporalis muscle and the pericranium, supplying that muscle and anastomosing with the middle temporal artery. The anterior deep temporal artery communicates with the lacrimal artery by means of small branches which perforate the zygomatic bone and great wing of the sphenoid. Certainly, the two temporal branches anastomose with each other.

**PTERYGOID BRANCHES.** The pterygoid branches vary in number and origin, and they supply the two pterygoid muscles.

**MASSETERIC ARTERY.** The masseteric artery arises from the maxillary between the neck of the mandible and the sphenomandibular ligament. It is a small vessel and passes laterally through the mandibular notch with the masseteric nerve to the deep surface of the masseter muscle. It supplies that muscle and anastomoses with the masseteric branches of the facial artery and with the transverse facial artery.

**BUCCAL ARTERY.** The buccal artery is a small vessel that courses, along with the buccal nerve, forward and downward between the medial pterygoid muscle and the insertion of the temporalis muscle to the external surface of the buccinator, which it supplies (Fig. 8-23). It anastomoses with branches of the facial, transverse facial, and infraorbital arteries.

**VARIATIONS.** The foregoing descriptions of the first and second parts of the maxillary artery apply to those specimens in which the maxillary artery courses superficial to the lateral pterygoid muscle. In about one-third of all cadavers, however, the vessel *passes deep to the lateral pterygoid*, which results in some variation in the origin of branches from the first two parts. In the latter situation, the deep auricular and anterior tympanic branches are unchanged. The masseteric and posterior deep temporal arteries come from a common trunk with the inferior alveolar artery from the first portion. The middle and accessory meningeal arteries arise from the second portion close to the foramen spinosum. The pterygoid, buccal, and anterior deep temporal branches also arise from the second portion, either separately or from a common trunk, deep to the lateral pterygoid muscle.

### Branches of the Third (or Pterygopalatine) Portion of the Maxillary Artery

The branches of the third part of the maxillary artery arise within the pterygopalatine fossa, and accompanied by branches of the maxillary division of the trigeminal nerve, they pass through foramina or bony canals. These branches are:

- Posterior superior alveolar
- Infraorbital
- Descending palatine
- Artery of the pterygoid canal
- Pharyngeal
- Sphenopalatine

#### POSTERIOR SUPERIOR ALVEOLAR ARTERY.

This vessel arises from the maxillary artery, frequently in conjunction with the infraorbital artery, just as the trunk of the maxillary is passing into the pterygopalatine fossa. Descending upon the tuberosity of the maxilla, the posterior superior alveolar artery divides into numerous branches, some of which supply the lining of the maxillary sinus while others enter the alveolar canals to supply the molar and premolar teeth. Still other branches continue anteriorly on the alveolar process to supply the gums. The vascular branches are accompanied in their course by branches of the posterior superior alveolar nerve, which are derived from the maxillary division of the trigeminal.

**INFRAORBITAL ARTERY.** The infraorbital artery arises as a branch from the maxillary artery as the latter vessel enters the pterygopalatine fossa, and frequently in conjunction with the posterior superior alveolar artery (Fig. 8-23). It runs along the infraorbital groove and canal with the infraorbital nerve and emerges on the face through the infraorbital foramen. In its course, the infraorbital artery gives off orbital, anterior superior alveolar, and facial branches.

The **orbital branches** arise in the infraorbital canal and they assist in the supply of the lacrimal gland and of the inferior rectus and inferior oblique muscles.

The **anterior superior alveolar branches** of the infraorbital artery, with branches of the middle and anterior superior alveolar nerves, descend through the grooves in the anterior wall of the maxilla (Fig. 8-23). Together the vessels and nerves enter the anterior alveolar canals to supply dental

branches to the upper incisor and canine teeth. Some branches also supply the mucous membrane of the maxillary sinus.

The **facial branches** of the infraorbital artery arise after the vessel emerges from the infraorbital foramen. On the anterior face some branches course upward to the medial angle of the orbit, supplying the lacrimal sac and anastomosing with the angular branch of the facial artery. Branches also descend toward the nose and anastomose with the dorsal nasal branch of the ophthalmic artery. Other branches descend between the levator labii superioris and the levator labii superioris alaeque nasi muscles and anastomose with the transverse facial and buccal arteries.

**DESCENDING PALATINE ARTERY.** The descending palatine artery arises from the maxillary artery in the pterygopalatine fossa and descends in the greater palatine canal with the greater palatine nerve, which is derived from the maxillary nerve and pterygopalatine ganglion. After emerging from the greater palatine foramen at the palate, the descending palatine artery becomes the **greater palatine artery**, having already given off several small **lesser palatine branches**.

The **greater palatine artery** courses anteriorly from the greater palatine foramen to the incisive canal in a groove called the greater palatine sulcus near the alveolar border on the oral surface of the hard palate. Branches of the vessel are distributed to the gums, palatine glands, and mucous membrane of the roof of the mouth. A terminal branch anastomoses with the nasopalatine branch of the sphenopalatine artery in the incisive canal.

The **lesser palatine arteries** arise from the descending palatine artery and course through the lesser palatine canals to emerge at the lesser palatine foramina. They then course medially, laterally, and posteriorly to supply the oral surface of the soft palate and the palatine tonsil. These vessels anastomose with the ascending palatine branch of the facial artery.

**ARTERY OF THE PTERYGOID CANAL.** This artery arises from the maxillary artery in the pterygopalatine fossa and enters the pterygoid canal (Vidian<sup>1</sup> canal) with the corre-

<sup>1</sup>Vidus Vidius (Latinized name of Guido Guidi, 1500-1569): An Italian physician and anatomist (Pisa).

sponding nerve. It is a long, slender branch that is distributed to the upper part of the pharynx and anastomoses with the ascending pharyngeal and sphenopalatine arteries. The artery of the pterygoid canal also supplies the auditory tube and sphenoidal sinus and sends into the tympanic cavity a small branch that anastomoses with the other tympanic arteries.

**PHARYNGEAL BRANCH.** The pharyngeal branch of the maxillary artery is quite small. It runs posteriorly in the palatovaginal canal with a nerve, the pharyngeal branch of the pterygopalatine ganglion, and is distributed to the auditory tube, the upper part of the pharynx, and the sphenoidal sinus.

**SPHENOPALATINE ARTERY.** The sphenopalatine artery is actually the terminal or continuation branch of the maxillary artery. It enters the nasal cavity through the sphenopalatine foramen at the posterior end of the superior meatus, close to the pterygopalatine ganglion, and is accompanied by lateral nasal, septal, and nasopalatine nerve branches from the maxillary nerve and pterygopalatine ganglion. Shortly after traversing the foramen, the sphenopalatine artery divides into posterior lateral nasal and posterior septal arteries.

The **posterior lateral nasal branches** run anteriorly, ramifying over the nasal conchae and meatuses that form the lateral wall of the nasal cavity. They also assist in the supply of the mucosa that lines the frontal, maxillary, ethmoidal, and sphenoidal sinuses.

The **posterior septal branches** arise from the sphenopalatine artery and, arching over the roof of the nasal cavity along the inferior surface of the sphenoid bone, anastomose with branches of the anterior and posterior ethmoidal arteries in the mucosa of the nasal septum. Other vessels ramify anteriorly and inferiorly on the septum. One branch, the **nasopalatine artery**, courses in a groove on the vomer with the nasopalatine nerve to the incisive canal, where it anastomoses with the greater palatine artery.

### *Internal Carotid Artery*

The **internal carotid artery** ascends in the neck, enters the base of the skull, opens into the cranial cavity, and supplies much of the cerebral hemisphere, the pituitary gland, the eyeball and other orbital structures, the anterior aspect of the forehead, and the exter-

nal nose. It consists of cervical, petrous, cavernous, and cerebral portions. The **cervical portion** of the internal carotid artery begins at the bifurcation of the common carotid opposite the upper border of the thyroid cartilage, and runs perpendicularly upward, anterior to the transverse processes of the first three cervical vertebrae, to reach the inferior surface of the petrous portion of the temporal bone (Fig. 8-24). The vessel then enters the carotid canal, becoming the **petrous portion**. It makes an abrupt turn forward and medially to the foramen lacerum. At the end of the carotid canal, the internal carotid artery curves upward, above the cartilage occupying the foramen lacerum, to enter the middle cranial fossa between the lingula and petrosal process of the sphenoid bone. The **cavernous portion** of the internal carotid artery is the first part of its course within the cranial cavity, where it is suspended between the layers of the dura mater that form the cavernous sinus (Fig. 8-25). Ascending toward the posterior clinoid process, the artery curves forward on the lateral aspect of the body of the sphenoid bone in the carotid sulcus. At the medial aspect of the anterior clinoid process, the vessel then perforates the part of the dura mater that forms the roof of the cavernous sinus. Thus, the cavernous portion of the internal carotid artery makes a double curvature like the letter S before piercing the dura to achieve the substance of the brain (Fig. 8-31). The **cerebral portion** of the artery then passes between the optic and oculomotor nerves and approaches the anterior perforated substance at the medial end of the lateral cerebral sulcus, where it gives off its intracerebral branches.

**CERVICAL PORTION.** The cervical portion of the internal carotid artery is comparatively superficial at its origin at the bifurcation of the common carotid artery (Fig. 8-24). Here the vessel is contained in the **carotid triangle**, and lies posterior and lateral to the external carotid artery, overlapped by the sternocleidomastoid muscle and covered by the deep fascia, platysma, and integument. It then passes deep to the parotid gland, being crossed by the hypoglossal nerve, the posterior belly of the digastric muscle, the stylohyoid muscle, and the occipital and posterior auricular branches of the external carotid artery. More superiorly, the internal carotid artery is separated from the external carotid by the styloglossus and stylopharyngeus muscles, the tip of the styloid process and the stylohyoid ligament, the glossopha-

**FIG. 8-24.** This dissection of the deep neck shows the internal carotid and vertebral arteries. Also note the courses and branches of the superior thyroid and lingual arteries.

ryngeal nerve, and the pharyngeal branch of the vagus. *Posteriorly*, it is in relation with the longus capitis muscle, the superior cervical ganglion of the sympathetic trunk with its internal carotid branch to the carotid plexus that surrounds the artery, and the superior laryngeal branch of the vagus nerve. *Laterally*, the internal carotid artery is related to the internal jugular vein and vagus nerve, the nerve lying on a plane posterior to the artery. *Medially*, the vessel is related to the wall of the pharynx, the superior laryngeal nerve, and the ascending pharyngeal artery. At the base of the skull, the glossopharyngeal, vagus, accessory, and hypoglossal nerves lie between the artery and the internal jugular vein.

**PETROUS PORTION.** When the internal carotid artery enters the carotid canal in the petrous portion of the temporal bone, it first ascends a short distance, then curves forward and medially, and again ascends as it leaves the canal to enter the cavity of the skull between the lingula and petrosal process of the sphenoid (Fig. 8-24). The artery lies at first anterior to the cochlea and tympanic cavity. It is separated from the tympanic cavity by a thin, bony lamella, which is cribriform in the young subject and often partly absorbed in old age. More anteriorly, it is separated from the trigeminal ganglion by a thin plate of bone that forms the floor of the fossa for the ganglion and the roof of the horizontal portion of the canal. Frequently this bony plate is more or less deficient; in these instances the ganglion is separated from the artery by fibrous membrane. The artery is

surrounded by a plexus of small veins that helps to drain the tympanic cavity and flows into the cavernous sinus and internal jugular vein, and by filaments of the carotid plexus of nerves, derived from the internal carotid branch of the superior cervical ganglion of the sympathetic trunk.

**CAVERNOUS PORTION.** In this part of its course, the internal carotid artery is situated between the layers of the dura mater forming the cavernous sinus, but it is covered by the lining membrane of the sinus (Figs. 8-25; 8-31). Initially, it ascends toward the posterior clinoid process, then passes forward by the side of the body of the sphenoid bone, and again curves upward on the medial aspect of the anterior clinoid process, perforating the dura mater that forms the roof of the sinus. This portion of the artery is surrounded by a plexus of sympathetic nerves, and directly on its lateral aspect courses the abducent nerve.

**CEREBRAL PORTION.** Having perforated the dura mater on the medial side of the anterior clinoid process, the internal carotid artery passes between the optic and oculomotor nerves toward the anterior perforated substance at the medial extremity of the lateral cerebral sulcus, where it divides into its cerebral branches (Figs. 8-28 to 8-32).

**VARIATIONS.** The length of the internal carotid varies according to the length of the neck and according to the point of bifurcation of the common carotid. It arises sometimes from the arch of the aorta. The course of the artery may be tortuous in-

**FIG. 8-25.** Diagram of the cavernous portion of the internal carotid artery. (From Taveras and Wood, *Diagnostic Neuroradiology*, 1964.)

stead of straight. A few instances have been reported in which this vessel was completely absent. In one such case, the common carotid artery ascended in the neck and gave off the usual branches of the external carotid, but the cranial portion of the internal carotid was replaced by two branches of the maxillary artery, which entered the skull through the foramen rotundum and foramen ovale and joined to form a single vessel.

#### Branches of the Internal Carotid Artery

The cervical portion of the internal carotid gives off no branches. Those from the other portions are:

Petrous Portion  
 Caroticotympanic  
 Pterygoid  
 Cavernous Portion  
 Cavernous

Hypophyseal  
 Ganglionic  
 Anterior meningeal  
 Cerebral Portion  
 Ophthalmic  
 Anterior cerebral  
 Middle cerebral  
 Posterior communicating  
 Anterior choroidal

#### CAROTICOTYMPANIC ARTERY

The caroticotympanic branch of the internal carotid artery is a small vessel that enters the tympanic cavity through a minute foramen on the posterior wall of the carotid canal. On the surface of the promontory it anastomoses with the anterior tympanic branch of the maxillary and with the stylo-mastoid branch of the posterior auricular artery.

### PTERYGOID BRANCH

The pterygoid branch of the internal carotid artery is a small inconstant vessel that passes into the pterygoid canal. It anastomoses with the pterygoid branch of the maxillary artery; this latter branch enters the opposite end of the canal from the pterygopalatine fossa.

### CAVERNOUS BRANCHES

The cavernous branches of the internal carotid artery are small vessels that supply the walls of the cavernous and inferior petrosal sinuses. Some of these arteries anastomose with branches of the middle meningeal artery.

### HYPOPHYSIAL ARTERIES

The superior and inferior hypophysial arteries branch from each internal carotid artery to supply the hypophysis (pituitary gland). Although these are small vessels, they are important because they supply a vital endocrine organ.

### GANGLIONIC BRANCHES

Several small ganglionic branches come off the internal carotid artery to supply the trigeminal ganglion.

### ANTERIOR MENINGEAL BRANCH

The anterior meningeal branch of the internal carotid artery is a small vessel that passes over the lesser wing of the sphenoid bone to supply the dura mater of the anterior cranial fossa. It anastomoses with the meningeal branch from the posterior ethmoidal artery.

### OPHTHALMIC ARTERY

The ophthalmic artery arises from the internal carotid, just as that vessel emerges from the dura mater that forms the cavernous sinus, on the medial aspect of the anterior clinoid process (Fig. 8-26). It enters the orbital cavity through the optic canal, inferior and lateral to the optic nerve. Deep to the superior rectus muscle, the ophthalmic artery passes obliquely over the optic nerve from lateral to medial to reach the medial wall of the orbit. The vessel then continues forward along the lower border of the superior oblique muscle to the medial end of the upper palpebral region where it divides into

two terminal branches, the **supratrochlear** and **dorsal nasal arteries**. As the ophthalmic artery crosses the optic nerve, it is accompanied by the nasociliary nerve and is separated from the frontal branch of the ophthalmic nerve by the superior rectus and levator palpebrae superioris muscles. The ophthalmic artery crosses deep to the optic nerve, rather than above, in about 15% of cases.

### Branches of the Ophthalmic Artery

The branches of the ophthalmic artery may be divided into an **orbital** group, distributed to orbital structures including the extraocular muscles and regions surrounding the orbit, and an **ocular** group, which supplies the eyeball (Fig. 8-26).

#### Orbital Group

- Lacrimal
- Supraorbital
- Posterior ethmoidal
- Anterior ethmoidal
- Medial palpebral
- Supratrochlear
- Dorsal nasal
- Muscular

#### Ocular Group

- Central artery of the retina
- Short posterior ciliary
- Long posterior ciliary
- Anterior ciliary

**LACRIMAL ARTERY.** The lacrimal artery arises from the ophthalmic artery soon after the latter vessel has entered the orbit. Sometimes it arises before the ophthalmic artery enters the orbit. The lacrimal artery is usually the first and often the largest branch derived from the ophthalmic (Fig. 8-26). It accompanies the lacrimal nerve along the superior border of the lateral rectus muscle and supplies the lacrimal gland. Its terminal branches, emerging from the gland, are distributed to the eyelids and conjunctiva. Of those supplying the eyelids, the two **lateral palpebral arteries** are of considerable size. They run medially in the upper and lower lids, respectively, and anastomose with the medial palpebral arteries to form an arterial arch. The lacrimal artery gives off one or two **zygomatic branches**. One of these passes through the zygomaticotemporal foramen to reach the temporal fossa and anastomoses

with the deep temporal branch of the maxillary artery. Another zygomatic branch appears on the cheek through the zygomaticofacial foramen and anastomoses with the transverse facial and zygomatico-orbital branches of the superficial temporal artery (Fig. 8-27). A **recurrent meningeal branch** of the lacrimal artery passes backward through the lateral part of the superior orbital fissure to the dura mater where it anastomoses with a branch of the middle meningeal artery. The lacrimal artery is sometimes derived from one of the anterior branches of the middle meningeal artery.

**SUPRAORBITAL ARTERY.** The supraorbital artery branches from the ophthalmic, the latter vessel crossing over the optic nerve (Fig. 8-26). Initially, it ascends in the orbit along the medial borders of the superior rectus and levator palpebrae superioris muscles to meet the supraorbital nerve. Accompanying the nerve between the periosteum and the levator palpebrae superioris, the artery courses forward in the orbit to the supraorbital foramen. Passing through the foramen, the supraorbital artery divides into a super-

ficial and a deep branch, which supply the integument, the muscles, and the pericranium of the forehead, anastomosing with the supratrochlear branch of the ophthalmic, the frontal branch of the superficial temporal (Fig. 8-27), the angular branch of the facial artery, and the artery of the opposite side. Within the orbit, the supraorbital artery supplies the superior rectus and the levator palpebrae superioris muscles and sends a branch across the pulley of the superior oblique muscle to help supply the region at the upper medial angle of the orbit. As the supraorbital artery courses through the supraorbital notch, a small branch passes through a foramen to supply the diploë of the frontal bone and the lining of the frontal sinus.

**POSTERIOR ETHMOIDAL ARTERY.** The posterior ethmoidal artery branches from the ophthalmic artery after the latter vessel has crossed to the medial side of the orbit (Fig. 8-26). It passes through the posterior ethmoidal canal and supplies the posterior ethmoidal air cells. Entering the cranium through a slitlike transverse aperture between the sphenoid bone and cribriform plate, it gives

**FIG. 8-26** The ophthalmic artery and some of its branches. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 1975.)

off a meningeal branch to the dura mater. Also, nasal branches descend into the nasal cavity through apertures in the cribriform plate. These anastomose with small vessels that come from the sphenopalatine branch of the maxillary artery.

**ANTERIOR ETHMOIDAL ARTERY.** The anterior ethmoidal branch of the ophthalmic artery accompanies the nasociliary nerve through the anterior ethmoidal canal. It supplies the anterior and middle ethmoidal cells and the frontal sinus and, entering the cranium, gives off a **meningeal branch** to the dura mater. The **nasal branches** descend into the nasal cavity through a slit lateral to the crista galli and, running along the groove on the inner surface of the nasal bone, supply branches to the lateral wall and septum of the nose. A terminal branch appears on the dorsum of the nose between the nasal bone and the lateral (upper) nasal cartilage.

**MEDIAL PALPEBRAL ARTERIES.** The medial palpebral arteries, two in number, superior and inferior, arise from the ophthalmic artery deep to the pulley of the superior oblique muscle. They descend from the orbit, one above the medial palpebral ligament and one below the ligament. These ves-

sels then encircle the eyelids near their free margins to form a superior and an inferior arch between the orbicularis oculi muscle and the tarsi. The **superior palpebral arch** anastomoses, at the lateral angle of the orbit, with the zygomatico-orbital branch of the superficial temporal artery, and with the superior of the two lateral palpebral branches from the lacrimal artery (Fig. 8-27). The **inferior palpebral arch** anastomoses, at the lateral angle of the orbit, with the inferior of the two lateral palpebral branches from the lacrimal artery and with the superficial temporal artery, and, at the medial part of the lid, with a twig from the angular branch of the facial artery. From this last anastomosis, a branch passes to the nasolacrimal duct, ramifying in its mucous membrane as far as the inferior meatus of the nasal cavity.

**SUPRATROCHLEAR ARTERY.** The supratrochlear artery is one of the terminal branches of the ophthalmic artery. It leaves the orbit at its medial angle with the supratrochlear nerve and, ascending on the forehead, helps to supply the integument, muscles, and pericranium in the region (Fig. 8-27). It anastomoses with the supraorbital

**Fig. 8-27.** Blood vessels of the eyelids, anterior view. 1, Branch of dorsal nasal artery that anastomoses with the angular artery. 2, Angular vein. 3, Angular branch of facial artery. 4, Facial vein. 5, Zygomatico-orbital branch of superficial temporal artery. 6, Middle temporal vein receiving orbital vein. 7, Frontal branch of superficial temporal artery. 8, Anastomosis of superior lateral palpebral branch of lacrimal artery with the anterior branch of superficial temporal artery. 9, Lacrimal artery giving rise to the superior and inferior lateral palpebral arteries. 10, Superior palpebral arch. 11, Superior palpebral artery. 12, Inferior palpebral artery. 13, Infraorbital artery. 14, Supraorbital artery and vein. 15, Supratrochlear artery.

artery and with the artery of the opposite side.

**DORSAL NASAL ARTERY.** The dorsal nasal artery is the other terminal branch of the ophthalmic, and it emerges from the orbit above the medial palpebral ligament (Fig. 8-27). After giving a twig to the superior part of the lacrimal sac, it divides into two branches. One of these crosses the root of the nose and anastomoses with the angular branch of the facial artery; the other runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the lateral nasal branch of the facial artery and with the artery of the opposite side.

**MUSCULAR BRANCHES.** Two groups of muscular branches are derived from the main trunk of the ophthalmic artery. The **superior muscular branches** supply the levator palpebrae superioris, superior rectus, and superior oblique muscles. The **inferior muscular group** passes forward between the optic nerve and the inferior rectus muscle and is distributed to the lateral, medial, and inferior rectus muscles as well as to the inferior oblique muscle. The anterior ciliary arteries are derived from the inferior muscular vessels, and additional muscular branches are given off from the lacrimal and supraorbital arteries.

**CENTRAL ARTERY OF THE RETINA.** This vessel is the first and one of the smallest arteries that branch from the ophthalmic. It also is the most important because it supplies the retina and because, beyond the optic disc, it is an end artery and does not anastomose with any other vessel. If its function is compromised, permanent retinal damage results. The central artery of the retina branches from the ophthalmic artery within the orbit, but close to the optic foramen. It pierces the dural sheath and courses for a short distance in the sheath with the optic nerve. At about 1.25 cm behind the eyeball it pierces the substance of the optic nerve obliquely and runs forward in the center of the nerve to the retina. Its mode of distribution in the retina will be described with the anatomy of the eye. The central retinal artery may be a branch of the lacrimal artery.

The **ciliary arteries** are divisible into three groups: the short and long posterior, and the anterior.

**SHORT POSTERIOR CILIARY ARTERIES.** There are usually more than six but fewer than ten short posterior ciliary arteries. They arise

from the ophthalmic artery or its branches and, surrounding the optic nerve, run to the posterior part of the eyeball. A number of the vessels may branch at this point before piercing the sclera around the entrance of the nerve in order to supply the choroid layer of the eyeball and the ciliary processes.

**LONG POSTERIOR CILIARY ARTERIES.** Usually two (but sometimes three) long posterior ciliary arteries arise from the ophthalmic artery on either side of the optic nerve (Fig. 8-26). Coursing forward with the optic nerve and the short posterior ciliary arteries, they pierce the posterior part of the sclera a short distance from the optic nerve and run along either side of the eyeball, between the sclera and choroid, to the ciliary muscle. Reaching the junction of the ciliary body and iris, each vessel divides into an upper and a lower branch. These branches form a vascular circle, the **circulus arteriosus major**, around the circumference of the iris. This circle sends numerous converging branches in the substance of the iris to its pupillary margin, where a second arterial circle, the **circulus arteriosus minor**, is formed.

**ANTERIOR CILIARY ARTERIES.** The anterior ciliary arteries are derived from muscular branches of the ophthalmic artery. These vessels course to the front of the eyeball along the tendons of the recti muscles, form a vascular zone beneath the conjunctiva, and then pierce the sclera a short distance from the sclerocorneal junction. They end by anastomosing with the circulus arteriosus major around the attached margin of the iris.

#### ANTERIOR CEREBRAL ARTERY

The anterior cerebral artery is one of the terminal branches of the internal carotid artery. It commences at the medial extremity of the lateral cerebral sulcus (Figs. 8-28; 8-29; 8-31). It passes anteriorly and medially across the anterior perforated substance, above the optic nerve, to the beginning of the longitudinal cerebral fissure. Here it comes into close relationship with the anterior cerebral artery of the opposite side, to which it is connected by a short trunk, the **anterior communicating artery**. From this point the two anterior cerebral arteries run side by side in the longitudinal cerebral fissure, curve around the genu of the corpus callosum and, turning backward, continue along the upper surface of the corpus callo-

**FIG. 8-28.** The arteries at the base of the brain. The temporal pole of the left cerebral hemisphere (reader's right) has been removed to reveal the course taken by the middle cerebral artery to the lateral sulcus of the cerebral cortex. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, 1975.)

**FIG. 8-29.** Branches of the *middle cerebral artery* to the lateral surface of the cerebral hemisphere.

**Fig. 8-30.** Medial surface of cerebral hemisphere, showing areas supplied by the three cerebral arteries.

sum to its posterior part. Here they end by anastomosing with the posterior cerebral arteries.

#### Branches of the Anterior Cerebral Artery

In addition to the **anterior communicating artery**, each anterior cerebral artery gives off **central branches** and, within the longitudinal cerebral fissure, several **cortical branches**. These latter vessels can best be seen coursing over the anterior medial surface of the cerebral hemisphere when the brain is sagittally sectioned through the midline. The branches of the anterior cerebral artery are:

- Anterior Communicating
- Anteromedial branches
- Central Branches
  - Recurrent (Medial striate)
- Cortical Branches
  - Orbital
  - Frontal
  - Parietal

**ANTERIOR COMMUNICATING ARTERY.** This artery connects the two anterior cerebral arteries across the commencement of the longitudinal fissure (Figs. 8-28; 8-32). Usually forming the anterior anastomosis of the **arterial circle of Willis**, the vessel varies in its configuration and may be completely absent, doubled, or even tripled. Its length averages about 4 mm, but varies greatly and it may be slender or wide. It gives off some anteromedial branches that course toward the optic chiasma.

**CENTRAL BRANCHES.** The first, or proximal, part of the anterior cerebral artery gives off several small vessels, which pierce the anterior perforated substance and the lamina terminalis, to supply the rostrum of the corpus callosum and the septum pellucidum. Additionally, a larger vessel, the **recurrent artery** (of Heubner<sup>1</sup>), also called the **medial striate artery**, arises just beyond the anterior communicating artery. Phylogenetically, it is one of the oldest of the cerebral arteries. It takes a rather long recurrent course laterally and backward over the anterior perforated substance and pierces the brain. Ascending in the anterior limb of the internal capsule, the recurrent artery supplies the lower anterior portion of the basal ganglia, including the lower part of the head of the caudate nucleus, the lower part of the frontal pole of the putamen, the frontal pole of the globus pallidus, and the anterior limb of the internal capsule up to the dorsal limit of the globus pallidus.

**CORTICAL BRANCHES.** Cortical branches of the anterior cerebral artery arise from that vessel as it courses backward over the corpus callosum (Fig. 8-29). They ramify over the anterior medial surface of the cerebral hemisphere and are named according to their distribution. Two or three **orbital branches** are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus, and medial orbital gyrus.

There are at least two large **frontal**

<sup>1</sup>Johann O. Heubner (1843-1926): A German pediatric neurologist (Berlin).

**branches**, the frontopolar and callosomarginal arteries. The *frontopolar* artery usually arises from the anterior cerebral just below the genu of the corpus callosum, and it supplies the medial aspect of the superior frontal gyrus, extending branches over the edge of the hemisphere to the lateral aspect of the superior and middle frontal gyri. The *callosomarginal* artery usually branches just anterior to the genu of the corpus callosum (Fig. 8-30). It supplies the corpus callosum, the cingulate gyrus, part of the medial surface of the superior frontal gyrus, and the precentral and postcentral gyri.

The anterior cerebral artery continues posteriorly in the cingulate sulcus as far as the parieto-occipital sulcus. Beyond the origin of the callosomarginal artery, the anterior cerebral is often called the *pericallosal* artery (Fig. 8-30). From this are derived the anterior and posterior **parietal branches**, which supply the medial surface of the precuneate gyrus and adjacent areas (Fig. 8-30).

#### MIDDLE CEREBRAL ARTERY

The middle cerebral artery is the largest branch of the internal carotid and one of its terminal branches (Figs. 8-28; 8-30; 8-31). Initially coursing laterally to enter the lateral sulcus (or Sylvian<sup>1</sup> fissure), it then runs backward and upward on the surface of the insula, where it divides into a number of branches that are distributed to the lateral surface of the cerebral hemisphere.

##### Branches of the Middle Cerebral Artery

Similar to the anterior cerebral, the middle cerebral artery gives off both central and cortical branches. The central branches are distributed to deep structures, while the cortical branches ramify more superficially in the sulci of the dorsal and lateral aspects of the cerebral cortex. The branches of the middle cerebral artery are subdivided as follows:

- Central Branches
  - Striate (Lateral striate)
- Cortical Branches
  - Orbital

Frontal  
Parietal  
Temporal

**CENTRAL BRANCHES.** The central branches of the middle cerebral artery arise soon after that vessel enters the lateral sulcus. Usually more than 10 but less than 15 delicate **striate** (lenticulostriate) **arteries** pierce the floor of the lateral sulcus to achieve subcortical structures. These vessels supply the corpus striatum, including the upper part of the head and entire body of the caudate nucleus, and much of the lentiform nucleus. Of the latter structure, the striate arteries supply the internal capsule above the level of the globus pallidus and they even extend into the thalamus. One of the larger striate arteries, which courses between the lentiform nucleus and external capsule and passes through the internal capsule to terminate in the caudate nucleus, is especially prone to hemorrhage. It has been called "the artery of cerebral hemorrhage" by Charcot,<sup>2</sup> and is the vessel frequently involved in cerebral stroke.

**CORTICAL BRANCHES.** Cortical branches of the anterior cerebral artery arise as the vessel courses posterosuperiorly in the lateral gyrus (Figs. 8-30; 8-31). The **orbital branches**, which include the *orbitofrontal* artery, supply the inferior frontal gyrus (Broca's<sup>3</sup> convolution) and the lateral part of the orbital surface of the frontal lobe. The ascending **frontal branches** supply the precentral gyrus, the middle frontal gyrus, and part of the inferior frontal gyrus. The anterior and posterior **parietal branches** ascend to the postcentral gyrus, the lower part of the superior parietal lobule, and the inferior parietal lobule. *Parietotemporal* and *parieto-occipital* branches supply the supramarginal and angular gyri, extending to the parieto-occipital sulcus (Fig. 8-29). The anterior, middle, and posterior **temporal branches** of the middle cerebral artery are distributed to the lateral surface of the temporal lobe, and they supply the superior, middle, and inferior temporal gyri from the temporal pole anteriorly up to the occipital gyri posteriorly (Fig. 8-29).

(From Taveras and Wood, *Diagnostic Neuroradiology*, 1964.)

#### POSTERIOR COMMUNICATING ARTERY

The posterior communicating artery arises from the posterior aspect of the internal carotid artery just before that vessel terminates into the anterior and middle cerebral arteries (Figs. 8-28; 8-32). It occasionally arises from the middle cerebral artery. Coursing backward over the optic tract and the oculomotor nerve, the posterior communicating artery anastomoses with the posterior cerebral artery, a branch of the basilar. It varies in size, being sometimes small and occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other and the vessel may even be doubled. **Central branches** of the posterior communicating artery immediately enter the base of the cer-

ebrum by piercing the posterior perforated substance, lateral and posterior to the infundibulum. These supply the anterior one-third of the posterior limb of the internal capsule, the medial thalamus, and the tissue adjacent to the third ventricle.

#### ANTERIOR CHOROIDAL ARTERY

The anterior choroidal artery arises from the posterior aspect of the internal carotid artery, near the origin of the posterior communicating artery. It is a relatively slender vessel that passes backward along the course of the optic tract and around the cerebral peduncles as far as the lateral geniculate body of the thalamus. It then courses beneath the uncinate gyrus, enters the choroid fissure to achieve the inferior horn of the lat-

**Fig. 8-32.** Diagram of the principal vessels that contribute to and branch from the arterial circulation at the base of the brain.

eral ventricle, and ramifies in the choroid plexus. Along its course, branches are supplied to the optic tract, the cerebral peduncles, the lateral geniculate body, the optic radiation, the tail of the caudate nucleus, the posterior limb of the internal capsule, the globus pallidus, the hippocampus and fimbria, and the choroid plexus.

#### ARTERIAL CIRCLE (OF WILLIS)

Because the mode of distribution of the vessels of the brain has an important bearing on a considerable number of the central nervous system lesions, it is important to consider a little more in detail the manner in which the vessels are distributed.

All the arterial blood to the brain is derived from the internal carotid and vertebral arteries, which at the base of the brain form

a remarkable anastomosis known as the **arterial circle of Willis** (Figs. 8-28; 8-32). It is formed *anteriorly* by the anterior cerebral arteries, branches of the internal carotid that are interconnected by the anterior communicating artery, and *posteriorly* by the two posterior cerebral arteries, which are branches of the basilar artery and are connected on either side with the internal carotid artery by the posterior communicating artery (Figs. 8-36; 8-37). The arterial circle underlies the hypothalamus, and the structures it encircles include the lamina terminalis, the optic chiasma, the infundibulum, the tuber cinereum, the mammillary bodies, and the posterior perforated substance. The three trunks that supply the cerebral hemisphere on each side all stem from the arterial circle. From its *anterior* part issue the two anterior cerebral arteries, from its *anterolat-*

eral parts stem the middle cerebral arteries, and from its posterior part arise posterior cerebral arteries. Each of these principal arteries contributes vessels that form a continuous complex network of capillaries, which is of different density in various parts of the central nervous system in relation to the varying requirements of the different regions. Thus, in comparison to white matter, the gray matter of the brain has a much higher oxygen consumption and, as expected, has a much denser capillary bed.

The cortical branches of the cerebral arteries that supply the surface of the brain anastomose quite freely, but significantly large arterial anastomoses of central branches are rare. There is no unequivocal evidence for the existence of arteriovenous anastomoses either in the pia or deep within the brain substance. True **end arteries** are arteries that have no connections with neighboring vessels. These are quite rare, but perhaps the best example is the central artery of the retina, which, when occluded, results in central retinal degeneration and a permanent loss of sight. Deeply coursing central vessels in the brain only anastomose with surrounding vessels at five capillary levels. Because of the high vulnerability of brain tissue to a lack of oxygen, a sudden occlusion of a main arterial trunk will result in an ischemic region consistent with the zone supplied by the occluded vessel. The inefficiency of the capillary anastomoses among centrally coursing arteries in the brain and their lack of practical benefit make them **functional end arteries**.

### **Subclavian Artery**

The **subclavian artery** supplies major vessels and branches to the brain, neck, anterior thoracic wall, and shoulder. The main trunk continues through the axilla as the **axillary artery** and achieves the arm, where it is called the **brachial artery**. The subclavian artery arises differently on the two sides. On the *right side* it stems from the brachiocephalic trunk, deep to the right sternoclavicular articulation (Figs. 8-20; 8-24; 8-33; 8-34). On the *left side* it arises from the arch of the aorta. The first part of the two vessels differs in length, course, direction, and relationships to neighboring structures. To facilitate their description, each subclavian artery is divided into three parts. The *first portion* ex-

tends from the origin of the vessel to the medial border of the scalenus anterior muscle; the *second portion* lies deep to this muscle; and the *third portion* extends from the lateral margin of the muscle to the outer border of the first rib where it becomes the axillary artery. The first portion of each vessel requires separate description; the second and third parts of the two subclavian arteries are practically the same.

**VARIATIONS.** The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The **right subclavian artery** may arise from the brachiocephalic trunk, in some instances above and in others below the sternoclavicular joint. The artery may arise as a separate trunk from the arch of the aorta, and may be either the first, second, third, or even the last branch derived from the arch. Generally, however, it is the first or last. When it is the first branch, the right subclavian occupies the ordinary position of the brachiocephalic trunk. When it is the second or third branch, the artery achieves its usual position by passing behind the right common carotid artery. When the right subclavian arises as the last branch, it stems from the left extremity of the arch and passes obliquely toward the right side, usually dorsal to the trachea, esophagus, and right common carotid (sometimes between the esophagus and trachea) to the upper border of the first rib, from which it follows its usual course. In rare instances, the right subclavian artery arises from the thoracic aorta, as far down as the fourth thoracic vertebra. It may occasionally perforate the scalenus anterior, and more rarely, it passes anterior to that muscle. Sometimes the subclavian vein passes with the artery behind the scalenus anterior. The artery may ascend as high as 4 cm above the clavicle, or may only ascend to the upper border of that bone; usually the right subclavian ascends higher than the left.

The **left subclavian artery** is occasionally joined at its origin with the left common carotid. It is more deeply placed than the right subclavian in the first part of its course and usually does not reach quite as high a level in the neck.

### **FIRST PART OF THE RIGHT SUBCLAVIAN ARTERY**

The first part of the right subclavian artery arises from the brachiocephalic trunk, deep to the cranial part of the right sternoclavicular articulation, and passes upward and laterally to the medial margin of the scalenus anterior (Figs. 8-20; 8-24). It arches a little above the clavicle, but the height to which it rises varies in different individuals.

**RELATIONS.** The first part of the right subclavian artery is covered *anteriorly* by the skin, superficial fascia, platysma, deep fascia, the clavicular origin of the sternocleidomastoid, as well as the sternohyoid, the sternothyroid, and another layer of the deep fascia. It is crossed by the internal jugular and vertebral veins, by the right vagus nerve and the sympathetic and vagal cardiac branches, and by the subclavian loop of the sympathetic trunk, called the **ansa subclavia**, which forms a ring around the vessel. The anterior jugular vein is directed laterally, anterior to the artery, but is separated from it by the sternohyoid and sternothyroid muscles. *Posteriorly* and *inferiorly*, the artery is in contact with the pleura, which separates it from the apex of the lung. Posteriorly is found the sympathetic trunk, the longus colli muscle, and the first thoracic vertebra. The right recurrent laryngeal nerve winds around the proximal part of the vessel.

#### FIRST PART OF THE LEFT SUBCLAVIAN ARTERY

The first part of the left subclavian artery arises from the arch of the aorta behind the left common carotid artery at the level of the

fourth thoracic vertebra (Figs. 8-33; 8-34). It ascends in the superior mediastinum to the root of the neck and then arches laterally to the medial border of the scalenus anterior muscle.

**RELATIONS.** The first part of the left subclavian artery is related *anteriorly* to the vagus, cardiac, and phrenic nerves which course parallel to it in the thorax. In addition, the left common carotid artery, left internal jugular and vertebral veins, and the commencement of the left brachiocephalic vein lie in front of the thoracic part of the subclavian artery; all these are covered by the sternothyroid, sternohyoid, and sternocleidomastoid muscles. *Posteriorly*, it is related to the esophagus, thoracic duct, left recurrent laryngeal nerve, inferior cervical ganglion of the sympathetic trunk, and longus colli muscle. More superiorly, however, the esophagus and thoracic duct lie to its right side, the latter ultimately arching over the vessel to join the angle of union between the subclavian and internal jugular veins. *Medial* to the left subclavian artery are the trachea, esophagus, thoracic duct, and left recurrent laryngeal nerve, while *lateral* to it are found the left mediastinal pleura and lung.

FIG. 8-33. The subclavian and axillary arteries with their branches. (Redrawn after Rauber-Kopsch.)

## SECOND PART OF THE SUBCLAVIAN ARTERY

The second part of the subclavian artery lies behind the scalenus anterior muscle (Figs. 8-20; 8-33). It is very short, measuring only about 2 cm in length, and forms the highest part of the arch achieved by the vessel in the root of the neck.

**RELATIONS.** The second part of the subclavian artery is covered *anteriorly* by the skin, superficial fascia, platysma, deep cervical fascia, sternocleidomastoid, and scalenus anterior. On the right side of the neck the phrenic nerve is separated from the second part of the artery by the scalenus anterior, while on the left side the nerve crosses the first part of the artery close to the medial edge of the muscle. *Posterior* to the vessel are the suprapleural membrane, the pleura, and the scalenus medius muscle; *superiorly*, are found the upper two trunks of the brachial plexus; and *inferiorly*, the pleura and lung. The subclavian vein lies anterior and inferior to the artery, separated from it by the scalenus anterior muscle.

## THIRD PART OF THE SUBCLAVIAN ARTERY

The third part of the subclavian artery continues its course inferolaterally from the lateral margin of the scalenus anterior to the outer border of the first rib, where it becomes the axillary artery (Figs. 8-20; 8-33). This, the most superficial portion of the vessel, crosses the supraclavicular or subclavian triangle (Fig. 8-19). The posterior border of the sternocleidomastoid muscle corresponds closely to the lateral border of the scalenus anterior. Thus, the third part of the subclavian artery is the most accessible for surgical procedures, since it can be achieved immediately lateral to the lower part of the posterior border of the sternocleidomastoid muscle.

**RELATIONS.** The third part of the subclavian artery is covered *anteriorly* by the skin, the superficial fascia, the platysma, the supraclavicular nerves, and the deep cervical fascia. The external jugular vein crosses its medial part and receives the suprascapular, transverse cervical, and anterior jugular veins, which frequently form a plexus in front of the artery. The nerve to the subclavius muscle descends between the artery and veins. The terminal part of the artery lies behind the clavicle and subclavius muscle and is crossed by the suprascapular vessels. The

subclavian vein is anterior and slightly inferior to the artery. *Posteriorly*, the third part of the subclavian artery lies on the inferior trunk of the brachial plexus, which intervenes between the vessel and the scalenus medius muscle. The upper two trunks of the brachial plexus and the inferior belly of the omohyoid muscle are superior and lateral to the artery. *Inferiorly*, it rests on the upper surface of the first rib.

**COLLATERAL CIRCULATION.** After ligation of the third part of the subclavian artery, collateral circulation is established mainly by anastomoses between the suprascapular, the descending ramus of the transverse cervical artery, and the subscapular artery. An anastomosis also exists between branches of the internal thoracic, lateral thoracic, and subscapular arteries.

## Branches of the Subclavian Artery

The branches of the subclavian artery and the vessels derived from these branches help to supply the brain, the neck, the thoracic wall, and the shoulder region. They include:

- Vertebral
- Basilar
- Thyrocervical trunk
- Internal thoracic
- Costocervical trunk
- Descending scapular

On the *left side*, all the branches except the descending scapular artery arise from the first part of the subclavian artery. On the *right side*, the costocervical trunk more frequently stems from the second part of the subclavian artery. On both sides, the vertebral artery, thyrocervical trunk, and internal thoracic artery arise close together at the medial border of the scalenus anterior. In most instances, there is a free interval of 1.25 to 2.5 cm between the commencement of the artery and the origin of the nearest branch. There is quite a variation in the origin of the vessels, which course laterally at the base of the posterior triangle of the neck, but usually one branch stems directly from the third part of the subclavian artery, which passes laterally behind the brachial plexus.

## VERTEBRAL ARTERY

The vertebral artery is the first and usually the largest branch of the subclavian, arising quite deep in the neck from the upper and posterior surface of the vessel (Figs. 8-20;

8-28; 8-32 to 8-36). It angles backward to the transverse process of the sixth cervical vertebra and runs superiorly through its foramen and the foramina in the transverse processes of the other upper five cervical vertebrae to the inferior surface of the skull. After penetrating the foramen in the atlas it

bends abruptly medialward around the lateral surface of the superior articular process to lie in a groove on the cranial surface of the posterior arch of the atlas. It passes under an arch in the posterior atlanto-occipital membrane (Figs. 5-11; 5-14), makes an abrupt bend to enter the cranial cavity through the

**FIG. 8-34.** Cervical and intracranial course of the left vertebral artery and its branches. (From Krayenbühl and Yasargil, *Cerebral Angiography*, 1968.)

foramen magnum, and, after a short course, joins the other vertebral to form the **basilar artery**.

**RELATIONS.** The vertebral artery may be divided into four parts. The **first part** courses upward and posteriorly in the neck between the longus colli and the scalenus anterior muscles. Anteriorly it is related to the internal jugular and vertebral veins, and it is crossed by the inferior thyroid artery. The left vertebral artery is crossed also by the thoracic duct. Posterior to the first part of the vertebral artery are the transverse process of the seventh cervical vertebra, the sympathetic trunk, and the cervicothoracic (stellate) ganglion. The **second part** of the vertebral artery ascends in the neck through the foramina in the transverse processes of the first six cervical vertebrae; it is surrounded by branches from the cervicothoracic sympathetic ganglion and by a plexus of veins that unite to form the vertebral vein at the caudal part of the neck. It is situated anterior to the ventral rami of the upper cervical nerves and pursues an almost vertical course as far as the foramen in the transverse process of the axis. After coursing through this foramen, it runs lateralward to the foramen in the transverse process of the atlas. The **third part** of the vertebral artery issues from the latter foramen on the medial aspect of the rectus capitis lateralis muscle and curves behind the lateral mass of the atlas, the anterior ramus of the first cervical nerve being on its medial side. It then lies in the groove on the superior surface of the posterior arch of the atlas and enters the vertebral canal by passing under the arched margin of the posterior atlanto-occipital membrane. This part of the artery is covered by the semispinalis capitis muscle and is contained in the **suboccipital triangle**, a region bounded by the rectus capitis posterior major, the obliquus superior, and the obliquus inferior (Fig. 6-22). The first cervical or suboccipital nerve lies between the artery and the posterior arch of the atlas. The **fourth part** of the vertebral artery pierces the dura mater and inclines medially to the anterior aspect of the medulla oblongata. It is placed between the hypoglossal nerve and the anterior root of the first cervical nerve and beneath the first digitation of the ligamentum denticulatum. At the inferior border of the pons, it unites with the vessel of the opposite side to form the **basilar artery**.

#### Branches of the Vertebral Artery

The branches of the vertebral artery may be divided into two sets: those given off in the neck and those within the cranium.

Cervical Branches  
Spinal  
Muscular

Cranial Branches  
Meningeal  
Posterior spinal  
Anterior spinal  
Posterior inferior cerebellar  
Medullary

**SPINAL BRANCHES.** Spinal branches of the vertebral artery enter the vertebral canal through the intervertebral foramina, and each divides into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord and its membranes, anastomosing with the other arteries of the spinal cord. The other divides into an ascending and a descending branch, which unite with similar branches from arteries of adjacent segments above and below, so that two lateral anastomotic chains are formed on the dorsal surfaces of the bodies of the vertebrae, near the attachment of the pedicles. From these anastomotic chains some branches are supplied to the periosteum and the bodies of the vertebrae, while others form communications with similar branches from the opposite side. Arising from these communications are small twigs that join similar branches, both above and below, to form a central anastomotic chain on the dorsal surface of the bodies of the vertebrae.

**MUSCULAR BRANCHES.** Muscular branches are given off the vertebral artery to the deep muscles of the neck as that vessel curves around the lateral mass of the atlas (Fig. 8-35). They anastomose with the occipital artery and with the ascending and deep cervical arteries.

**MENINGEAL BRANCH.** One or two small meningeal branches arise from the vertebral artery at the level of the foramen magnum. They ramify between the bone and dura mater in the cerebellar fossa, and they supply the falx cerebelli.

**POSTERIOR SPINAL ARTERY.** The posterior spinal artery may originate from the intracranial portion of the vertebral artery at the side of the medulla oblongata, or from the posterior inferior cerebellar artery. Passing dorsally, it descends on the medulla beyond the spinomedullary junction, lying ventral to the dorsal roots of the spinal nerves. As the vessel descends on the posterolateral aspect of the spinal cord, it becomes reinforced by a succession of spinal branches and is thereby continued to the end of the spinal

cord and the cauda equina. Branches from the posterior spinal arteries form a free anastomosis around the dorsal roots of the spinal nerves, communicating by means of tortuous transverse branches with vessels of the opposite side. Close to its origin each posterior spinal artery gives off an ascending branch that ramifies in the lateral wall of the fourth ventricle.

**ANTERIOR SPINAL ARTERY.** The anterior spinal artery is a vessel formed by the junction of two branches, one from each vertebral artery (Figs. 8-28; 8-32; 8-35; 8-36). The branches arise near the point at which the two vertebral arteries join to form the basi-

**Fig. 8-35.** Angiogram of the vertebral artery showing the anterior spinal artery descending in the spinal cord (open arrows) and anastomotic radicular branches (solid arrows) which enter the cord with the cervical roots of the spinal nerves. (From Newton and Mani, *Radiology of the Skull and Brain*, 1974.)

lar artery. Each branch descends ventral to the medulla and generally unites within about 2 cm from its origin at about the level of the foramen magnum. The single trunk thus formed descends in the anterior median fissure of the spinal cord, and it is reinforced by a succession of small branches that enter the vertebral canal through the intervertebral foramina. These branches are derived from the vertebral and the ascending cervical branch of the inferior thyroid artery in the neck, the intercostal arteries in the thorax, and the lumbar, ilio-lumbar, and lateral sacral arteries of the posterior abdominal and pelvic wall. These vessels anastomose by means of ascending and descending branches to form a single anterior median artery, which extends as far as the lower part of the spinal cord and is continued as a slender twig on the filum terminale. Coursing within the pia mater, the anterior spinal artery helps to supply that membrane and the substance of the spinal cord, and it also sends off branches at its caudal part to be distributed to the cauda equina.

**POSTERIOR INFERIOR CEREBELLAR ARTERY.**

The posterior inferior cerebellar artery is the largest branch of the vertebral artery (Figs. 8-28; 8-32; 8-33; 8-36). Although this artery varies greatly in its course and distribution, it most often arises from the vertebral approximately 1.5 cm before the vertebrals unite to form the basilar, but occasionally it is absent. It courses at first laterally and then posteriorly around the lower end of the olive of the medulla oblongata. Passing between the rootlets of the glossopharyngeal and vagus nerves, over the inferior peduncle to the inferior surface of the cerebellum, the artery divides into two branches. The **medial branch** is continued posteriorly to the notch between the two hemispheres of the cerebellum, while the **lateral branch** supplies the inferior surface of the cerebellum as far as its lateral border. Here it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from the posterior inferior cerebellar artery also supply penetrating branches to the medulla as well as to the choroid plexus of the fourth ventricle.

**MEDULLARY BRANCHES.** Several small medullary vessels branching from the vertebral artery are distributed to the medulla oblongata.

**BASILAR ARTERY**

The basilar artery is formed by the junction of the two vertebral arteries (Figs. 8-28; 8-32; 8-34; 8-36). As a single vascular trunk, it courses superiorly in a shallow median groove on the anterior surface of the pons. It extends from the pontomedullary sulcus, which demarcates the rostral medulla and caudal pons, to the level of the emerging oculomotor nerves from the caudal mid-brain. The basilar artery is often tortuous and may be slightly curved in its rostral course along the brain stem. Its length varies from 2.5 to 4.0 cm, and after passing between the two oculomotor nerves, the artery terminates by dividing into the two posterior cerebral arteries.

**Branches of the Basilar Artery**

In its course the basilar artery gives off the following branches on both sides:

Pontine  
Labyrinthine  
Anterior inferior cerebellar

Superior cerebellar  
Posterior cerebral

**PONTINE BRANCHES.** The pontine branches of the basilar artery consist of a number of small vessels that supply the pons and mid-brain (Fig. 8-32). Median vessels arise at right angles from the posterior aspect of the basilar and enter the pons along its anterior median groove. Transverse branches arise from the posterolateral and lateral aspects of the basilar, and in their circumferential course around the brain stem, they send penetrating vessels into the pons.

**LABYRINTHINE ARTERY.** Also known as the internal auditory artery, the labyrinthine artery is a long slender branch that arises near the middle of the basilar artery (Figs. 8-28; 8-32). It accompanies the facial and vestibulocochlear nerves through the internal acoustic meatus and is distributed to the internal ear. It often arises from the anterior inferior cerebellar artery.

**ANTERIOR INFERIOR CEREBELLAR ARTERY.** The anterior inferior cerebellar artery generally arises from the lower third of the basilar artery (Figs. 8-28; 8-34; 8-36). Its course is

**Fig. 8-36.** The ventral surface of the medulla and pons showing the vertebral and basilar arteries and their branches. (From Taveras and Wood, *Diagnostic Neuroradiology*, 1964.)

somewhat variable, but initially it usually courses laterally and posteriorly and lies in contact with either the dorsal (33%) or ventral (67%) aspect of the abducens nerve. Continuing its downward course, the vessel frequently lies ventral to the roots of the facial and vestibulocochlear nerves. Often it forms a loop in relation to these nerves at the level of the internal acoustic meatus. The main trunk of the anterior inferior cerebellar artery sends small branches into the lateral aspect of the pons. At the cerebellopontine angle, the artery divides into **lateral** and **medial branches**, which are distributed to the anterolateral and anteromedial parts of the inferior surface of the cerebellum. The anterior inferior cerebellar artery anastomoses with the posterior inferior cerebellar branch of the vertebral artery.

**SUPERIOR CEREBELLAR ARTERY.** The superior cerebellar artery arises a few millimeters proximal to the termination of the basilar artery (Figs. 8-28; 8-34; 8-36). It passes lateralward immediately caudal to the oculomotor nerve, which separates it from the posterior cerebral artery. It then winds around the cerebral peduncle, close to the trochlear nerve. Arriving at the superior surface of the cerebellum, which it supplies, it divides into branches that ramify in the pia mater and anastomose with those of the inferior cerebellar arteries. Several branches go to the midbrain, the pineal body, the anterior medullary velum, and the tela choroidea of the third ventricle.

**POSTERIOR CEREBRAL ARTERY.** Embryologically, the posterior cerebral artery develops as a branch of the internal carotid artery and, in some instances, remains a branch of the internal carotid in the adult. In most instances, however, the posterior cerebral arteries are the terminal branches of the basilar artery, and they maintain their attachment to the internal carotid on each side by way of the posterior communicating artery, forming the posterior part of the arterial circle of Willis. The posterior cerebral artery is larger than the superior cerebellar artery, and it is separated from that vessel near its origin by the oculomotor nerve (Figs. 8-28; 8-32; 8-36). Passing laterally, parallel to the superior cerebellar artery and receiving the posterior communicating artery from the internal carotid, it winds around the cerebral peduncle and reaches the tentorial surface of the occipital lobe of the cerebrum,

where it breaks up into branches for the supply of the temporal and occipital lobes. The posterior cerebral artery gives off central, posterior choroidal, and cortical branches.

**CENTRAL BRANCHES.** The central branches of the posterior cerebral artery can be divided into mesencephalic and thalamic branches. The **mesencephalic branches** arise from the posterior surface of each posterior cerebral artery and enter the posterior perforated substance to supply the interpeduncular region of the midbrain as well as the cerebral peduncles themselves. Such important structures as the oculomotor nuclei, mesencephalic reticular formation, substantia nigra, and the corticospinal paths at the midbrain level are supplied by these vessels. Additionally, *circumflex mesencephalic branches* pass around the midbrain to supply perforating arteries to the peduncles and to the substantia nigra, as well as longer branches to dorsal tegmental structures. Anterior and posterior **thalamic branches** arise from the posterior cerebral artery to perforate and supply both hypothalamic and thalamic centers (Fig. 8-37). The *anterior thalamic branches* supply the more caudal parts of the hypothalamus, including the mammillary bodies, as well as the optic tract. Certain of these vessels ascend through the hypothalamus to achieve the thalamus and thereby supply its anterior and ventromedial nuclei. Some *posterior thalamic branches* ascend through the posterior perforated substance to supply the more posterior thalamic nuclei, while posterior thalamogeniculate vessels course more superiorly to supply the geniculate bodies (Newton and Potts, 1974).

**POSTERIOR CHOROIDAL BRANCHES.** Two or more posterior choroidal branches arise from the posterior cerebral artery. The (posterior) *medial choroidal artery* branches near the origin of the posterior cerebral and courses dorsally and medially around the midbrain, supplying the corpora quadrigemina and the pineal gland (Figs. 8-37; 8-38). It then courses forward to supply the roof of the third ventricle, ramifies within the choroid plexus of that ventricle, and sends penetrating branches to the dorsal medial nucleus of the thalamus and frequently to the pulvinar. The (posterior) *lateral choroidal artery* may arise singly or as multiple vessels from the posterior cerebral, but it may also arise from the parieto-occipital branch of the posterior cerebral artery

**Fig. 8-37.** The branches of the posterior cerebral artery as viewed on the medial aspect of the right cerebral hemisphere. (From Krayenbühl and Yasargil, *Cerebral Angiography*, 1968.)

(Figs. 8-37; 8-38). One branch of the lateral choroidal artery courses laterally and enters the choroid fissure to supply the choroid plexus of the temporal horn. Another branch courses back behind the pulvinar to supply the choroid plexus of the lateral ventricle. Branches perforate into the thalamus to supply the dorsomedial nucleus, the pulvinar, and the lateral geniculate bodies. Branches of the posterior medial and lateral choroidal arteries anastomose with each other (Newton and Potts, 1974).

**CORTICAL BRANCHES.** Generally there are

four cortical branches of the posterior cerebral artery that supply the medial surface of the temporal and occipital lobes. They are the anterior temporal, posterior temporal, parieto-occipital, and occipital (calcarine) branches (Figs. 8-30; 8-31; 8-37). The anterior temporal branch extends laterally and anteriorly beneath the temporal lobe to supply the uncus and parahippocampal gyrus, where it anastomoses with the anterior temporal branch of the middle cerebral artery. The posterior temporal branch courses back along the parahippocampal gyrus to supply

**Fig. 8-38.** The course and branches of the posterior cerebral artery after it arises from the basilar artery. (From Wilson, *The Anatomic Foundation of Neuroradiology of the Brain*, 1972.)

the medial and lateral occipitotemporal gyri. The *parieto-occipital branch* usually divides into a number of smaller vessels that course superiorly and posteriorly on the medial surface of the cerebral hemisphere to supply the precuneate and cuneate gyri. The *occipital (calcarine) branch* supplies the primary visual cortex by following the calcarine sulcus as far as the occipital pole. It supplies the lingual and cuneate gyri and frequently the occipital and parieto-occipital branches overlap somewhat in their distribution to the visual cortical receiving area.

### THYROCERVICAL TRUNK

The thyrocervical trunk is a short thick vessel that arises from the first portion of the subclavian artery, close to the medial border of the scalenus anterior muscle (Figs. 8-20; 8-33; 8-34; 8-39; 8-40). Almost immediately it divides into the following three arteries:

- Inferior thyroid
- Suprascapular
- Transverse cervical

### Inferior Thyroid Artery

The inferior thyroid artery courses cranially anterior to the vertebral artery and longus colli muscle. It then loops medially dorsal to the carotid sheath and its contents, as well as to the sympathetic trunk; the middle cervical ganglion often rests on the vessel (Figs. 8-20; 8-33; 8-39; 8-40). Reaching the lower border of the thyroid gland, the inferior thyroid artery divides into two branches, which supply the inferior parts of the gland and anastomose with the superior thyroid artery and with the inferior thyroid artery of the opposite side. The recurrent laryngeal nerve courses superiorly in the neck, generally dorsal but occasionally ventral to the artery.

### Branches of the Inferior Thyroid Artery

In addition to the terminal branches that supply the thyroid gland, the inferior thyroid artery gives off the following branches:

- Inferior laryngeal
- Tracheal
- Esophageal
- Ascending cervical
- Muscular

**INFERIOR LARYNGEAL ARTERY.** The inferior laryngeal artery ascends upon the trachea to the dorsal part of the larynx under cover of the inferior pharyngeal constrictor muscle and in company with the recurrent laryngeal nerve. It supplies the muscles and mucous membrane of this region of the larynx, anastomosing with the branch from the opposite side and with the superior laryngeal branch of the superior thyroid artery.

**TRACHEAL BRANCHES.** Tracheal branches of the inferior thyroid artery are distributed to the trachea and anastomose inferiorly with the bronchial arteries and superiorly with tracheal branches from the superior thyroid artery.

**ESOPHAGEAL BRANCHES.** The esophageal branches of the inferior thyroid artery supply the esophagus and anastomose with esophageal branches that arise directly from the aorta.

**ASCENDING CERVICAL ARTERY.** The ascending cervical artery arises from the inferior thyroid as that vessel passes dorsal to the carotid sheath (Figs. 8-20; 8-33; 8-39; 8-40). It may arise directly from the thyrocervical trunk. It ascends in the neck on the anterior tubercles of the transverse processes of the cervical vertebrae in the interval between the scalenus anterior and longus capitis muscles. Lying parallel and medial to the phrenic nerve, the ascending cervical artery supplies some deep muscles of the neck with twigs that anastomose with branches of the vertebral artery. In addition, it sends one or two **spinal branches** into the vertebral canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebrae in the same way as spinal branches are distributed from the vertebral artery. It anastomoses with the ascending pharyngeal and occipital arteries, with branches of the external carotid artery, and with the vertebral artery.

**MUSCULAR BRANCHES.** Muscular branches of the inferior thyroid artery supply the infrahyoid, the longus colli, the scalenus anterior, and the inferior pharyngeal constrictor muscles.

### Suprascapular Artery

The suprascapular artery passes initially downward and laterally across the scalenus anterior and the phrenic nerve, being cov-

**FIG. 8-39.** The subclavian artery and its branches showing the so-called Type I pattern in which the transverse cervical artery branches from the thyrocervical trunk, crosses the lower neck, and divides into a superficial branch, which ascends in the neck, and a deep branch, which descends to the medial scapular region.

ered by the sternocleidomastoid muscle (Figs. 8-20; 8-33; 8-34; 8-39; 8-40). It then crosses in front of the subclavian artery and the brachial plexus, and running deep to and parallel with the clavicle and subclavius muscle and deep to the inferior belly of the omohyoid muscle, it reaches the superior border of the scapula. It passes over the superior transverse scapular ligament by which it is separated from the suprascapular nerve to enter the supraspinous fossa. Within the fossa it lies directly on the bone and sends branches to the overlying supraspinatus muscle, which it supplies. It then winds laterally around the neck of the scapula, descending through the great scapular notch under cover of the inferior transverse scapular ligament to reach the infraspinous fossa. Here it supplies the infraspinatus muscle and anastomoses with the scapular circumflex branch of the subscapular artery and the deep branch of the transverse cervi-

cal (descending scapular) artery. Besides distributing branches to the sternocleidomastoid, subclavius, and neighboring muscles, the suprascapular artery gives off a **suprasternal branch**, which crosses over the sternal end of the clavicle to the skin of the chest, and an **acromial branch**, which pierces the trapezius to supply the skin over the acromion, anastomosing with the acromial branch of the thoracoacromial artery. As the artery passes over the superior transverse scapular ligament, it sends a branch into the subscapular fossa, where it ramifies beneath the subscapularis muscle and anastomoses with the subscapular artery and deep branch of the transverse cervical (descending scapular) artery. It also sends **articular branches** to the acromioclavicular and shoulder joint and **nutrient branches** to the clavicle and scapula. In about 25% of cadavers studied, the suprascapular artery arises from the third part of the subclavian artery.

**Fig. 8-40.** The subclavian artery and its branches showing the so-called Type II pattern in which the superficial cervical artery is derived from the thyrocervical trunk and the descending scapular artery arises from the third part of the subclavian. These vessels are distributed to the same regions as the superficial and deep branches of the transverse cervical artery of the Type I pattern.

### Transverse Cervical Artery

The transverse cervical artery, in more than half the specimens studied, arises as a single vessel and eventually divides into two main branches, a superficial and a deep branch (Fig. 8-39). In these instances, the transverse cervical artery stems from the thyrocervical trunk, but it may occasionally arise as a single vessel directly from the third part of the subclavian artery rather than from the thyrocervical trunk. When the transverse cervical artery does arise from the thyrocervical trunk, it passes laterally across the posterior cervical triangle in a position somewhat above and behind the suprascapular artery. Medially, it crosses superficial to the scalenus anterior and phrenic nerve and lies deep to the sternocleidomastoid muscle. Laterally, it crosses the trunks of the brachial plexus and is cov-

ered only by the platysma, the investing layer of deep fascia, and the inferior belly of the omohyoid. As the artery approaches the anterior margin of the trapezius, it divides into a **superficial branch** and a **deep branch**.

In another large percentage of cadavers studied, there is no transverse cervical artery as such, branching either from the thyrocervical trunk or from the third part of the subclavian artery (Fig. 8-40). In these instances, the regions supplied by the superficial and deep branches of the transverse cervical artery become supplied by other arteries. Thus, the *superficial branch of the transverse cervical artery* becomes replaced by the **superficial cervical artery**, and the *deep branch of the transverse cervical artery* becomes replaced by the **descending scapular artery** (also known as the dorsal scapular artery, a term no longer found in the *Nomina Anatomica*).

Because these two different vascular patterns are about equally represented in the specimens studied, the descriptions of the superficial and deep branches of the transverse cervical artery will be followed by descriptions of the superficial cervical artery and the descending scapular artery.

**SUPERFICIAL BRANCH OF TRANSVERSE CERVICAL ARTERY.** The superficial branch of the transverse cervical artery is the principal blood supply to the trapezius muscle (Fig. 8-39). Lying along the deep surface of this muscle, the artery divides into an ascending and a descending branch. The ascending branch courses superiorly along the anterior border of the trapezius, distributing branches to it and to neighboring muscles and anastomosing with the superficial part of the descending branch of the occipital artery. The descending branch accompanies the accessory nerve along the deep surface of the trapezius, supplying the muscle.

**DEEP BRANCH OF TRANSVERSE CERVICAL ARTERY.** The deep branch of the transverse cervical artery supplies vessels to the levator scapulae and neighboring deep cervical muscles (Fig. 8-39). Passing deep to the levator scapulae muscle, it reaches the superior angle of the scapula and passes down along the vertebral border to the inferior angle, lying deep to the rhomboid muscles and accompanying the dorsal scapular nerve. It supplies muscular branches to the rhomboid, serratus posterior superior, subscapularis, supraspinatus, and infraspinatus muscles and to other neighboring muscles. These branches anastomose with the suprascapular, subscapular, and circumflex scapular arteries.

**SUPERFICIAL CERVICAL ARTERY.** The superficial cervical artery is seen in cadavers that do not have a transverse cervical artery, and it corresponds to the superficial branch of the transverse cervical (Fig. 8-40). It arises from the thyrocervical trunk, as would the transverse cervical artery, but no vessel comparable to the deep branch of the transverse cervical artery stems from the superficial cervical artery. It passes laterally across the posterior triangle of the neck, deep to the sternocleidomastoid muscle and superficial to the scalenus anterior muscle and phrenic nerve. It then courses cranially across the trunks of the brachial plexus to the anterior border of the trapezius muscle, where its ascending branch supplies the upper part of

the trapezius and neighboring muscles, anastomosing with the superficial descending branch of the occipital artery, and its descending branch lies against the deep surface of the trapezius, supplying it with branches and accompanying the accessory nerve.

**DESCENDING SCAPULAR ARTERY.** The descending scapular artery (sometimes still carelessly called the dorsal scapular artery) is observed in specimens in which there is no transverse cervical artery. Its distribution corresponds to that of the deep branch of the transverse cervical artery (Fig. 8-40). When present, the descending scapular artery has an independent origin from the third part of the subclavian artery instead of from the thyrocervical trunk. Occasionally it may arise from the second part of the subclavian artery. It passes upward for a short distance, then loops around the brachial plexus, frequently passing between the anterior and posterior divisions of the upper trunk. The vessel then courses downward toward the scapula and, at the border of the levator scapulae, divides into an ascending and a descending branch. The ascending branch supplies the levator scapulae and neighboring deep cervical muscles. The descending branch, usually double, passes deep to the levator scapulae to the superior angle of the scapula, and then descends anterior to the rhomboid muscles along the medial border of the bone as far as its inferior angle. When there are two descending branches, the more medial is accompanied by the dorsal scapular nerve, while the larger, more lateral vessel lies on the costal surface of the serratus anterior muscle. The descending branch(es) supplies the rhomboid, latissimus dorsi, and trapezius muscles and anastomoses with the suprascapular and subscapular arteries, and with the posterior branches of some of the intercostal arteries.

#### INTERNAL THORACIC ARTERY

The internal thoracic artery arises from the first portion of the subclavian artery about 2 cm above the clavicle, opposite the thyrocervical trunk and close to the medial border of the scalenus anterior muscle (Fig. 8-41). It descends behind the cartilages of the upper six ribs at a distance of about 1.25 cm from the margin of the sternum. At the level

of the sixth intercostal space, the internal thoracic artery terminates by dividing into the musculophrenic and superior epigastric arteries.

**RELATIONS.** As it descends toward the sternum, the **internal thoracic artery** lies deep to the sternal end of the clavicle, the subclavian and internal jugular veins, and the first costal cartilage. As it enters the thorax, it passes close to the lateral aspect of the brachiocephalic vein, and the phrenic nerve crosses it obliquely from its lateral to its medial aspect. Below the first costal cartilage, it descends almost vertically to its point of bifurcation. It is covered anteriorly by the cartilages of the first six ribs, by the intervening internal intercostal muscles, and by external intercostal membranes. The vessel is crossed by the terminal portions of the first six intercostal nerves. Between the artery and the pleura is a deep fascial plane as far as the third costal cartilage, and below this level the transversus thoracis muscle separates the vessel from the pleura. It is accompanied by a chain of lymph nodes and by a pair of veins that unite to form a single vessel, which ascends medial to the artery and ends in the corresponding brachiocephalic vein.

#### Branches of the Internal Thoracic Artery

Among other structures, the branches of the internal thoracic artery help to supply the pericardium, pleura, thymus, and bronchi, as well as the transverse thoracis, intercostal, and pectoralis major muscles, the rectus abdominis and other anterior abdominal muscles, the diaphragm, and even the mammary gland in the female. Its branches are:

- Pericardiophrenic
- Mediastinal
- Thymic
- Bronchial
- Sternal
- Anterior intercostal
- Perforating
- Lateral costal branch
- Musculophrenic
- Superior epigastric

**PERICARDIOPHRENIC ARTERY.** The pericardiophrenic artery is a long, slender, and somewhat tortuous vessel that arises from the internal thoracic artery just after the latter vessel has entered the thorax (Figs. 7-24; 8-39; 8-40). Accompanying the phrenic nerve to the diaphragm, which it helps to supply, the pericardiophrenic artery courses between the pleura and pericar-

dium, and it sends branches to both these structures. It anastomoses with the musculophrenic and the superior and inferior phrenic arteries (Fig. 7-24).

**MEDIASTINAL BRANCHES.** The mediastinal branches of the internal thoracic artery are small vessels, distributed to the areolar tissue and lymph nodes in the anterior mediastinum, and they also supply the upper part of the sternocostal surface of the pericardium.

**THYMIC BRANCHES.** In the adult, the thymic branches are small and supply the remains of the thymus. In the infant and child, however, they are more significant vessels.

**BRONCHIAL BRANCHES.** The bronchial branches from the internal thoracic artery, when present, are distributed to the bronchi and lower part of the trachea.

**STERNAL BRANCHES.** Sternal branches of the internal thoracic artery are distributed to the transversus thoracis muscle and to the posterior surface of the sternum.

The mediastinal, pericardial, bronchial, and sternal branches, together with some twigs from the pericardiophrenic, anastomose with branches from the posterior, intercostal, and bronchial arteries from the thoracic aorta to form a **subpleural mediastinal plexus**.

**ANTERIOR INTERCOSTAL ARTERIES.** The anterior intercostal branches of the internal thoracic artery supply the first five or six intercostal spaces, the remaining more caudal spaces being supplied by the musculophrenic branch. In each space, two small arteries pass laterally from the internal thoracic, one each at the upper and lower margins of the intercostal space (Fig. 8-41). They supply the intercostal muscles and finally anastomose with the external intercostal arteries from the aorta. At first the anterior intercostal arteries lie between the pleura and the internal intercostal muscles, and then more laterally between the innermost and internal intercostal muscles. Some branches perforate through the external intercostal muscles to supply the pectoral muscles and the mammary gland.

**PERFORATING BRANCHES.** The perforating branches from the internal thoracic artery pierce the anterior thoracic wall in the first five or six intercostal spaces close to the sternum (Fig. 8-41). These vessels course with the anterior cutaneous branches of the intercostal nerves and penetrate the intercostal

**FIG. 8-41.** The left internal thoracic artery and its branches. Observe the anastomosis between the superior and inferior epigastric arteries.

muscles and pectoral fascia to achieve the deep surface of the pectoralis major muscle. They curve laterally as they become more superficial and supply the pectoralis major muscle and the skin. The arteries of the second, third, and fourth spaces give **mammary branches** to the breast in the female and become greatly enlarged during lactation.

**LATERAL COSTAL BRANCH.** Although frequently absent or very small, the lateral costal branch arises at times from the internal thoracic artery near the first rib. When present (about 25% of cadavers), it descends lateral to the costal cartilages and behind the ribs and anastomoses with the upper anterior intercostal arteries.

**MUSCULOPHRENIC ARTERY.** The musculophrenic artery is one of the two terminal branches of the internal thoracic artery, and it is directed obliquely downward and laterally, behind the cartilages of the eighth, ninth, and tenth ribs (Fig. 8-41). It perforates the diaphragm near the eighth or ninth costal cartilage, and ends, considerably reduced in size, opposite the last intercostal space. It gives off two anterior intercostal branches to the seventh, eighth, and ninth intercostal spaces. These diminish in size as the intercostal spaces decrease in length and are distributed in a manner precisely similar to the anterior intercostals that branch directly from the internal thoracic. Some other

branches of the musculophrenic artery course to the lower part of the pericardium, some course dorsally to the diaphragm, and still others course down to the abdominal muscles.

**SUPERIOR EPIGASTRIC ARTERY.** The superior epigastric artery is a terminal branch of the internal thoracic artery, and it continues in the original direction of the parent vessel (Fig. 8-41). It descends through the interval between the costal and sternal attachments of the diaphragm and enters the sheath of the rectus abdominis muscle. At first the superior epigastric muscle lies behind the rectus muscle, but then perforates and supplies the muscle and thereby anastomoses with the inferior epigastric artery from the external iliac. Branches eventually perforate the anterior layer of the rectus sheath and supply other anterior abdominal wall muscles and the overlying skin. A small branch passes in front of the xiphoid process and anastomoses with the artery of the opposite side. The superior epigastric artery also gives some twigs to the diaphragm, while from the artery on the right side, small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

#### **COSTOCERVICAL TRUNK**

On the left side the costocervical trunk arises from the first part of the subclavian artery, medial to the scalenus anterior muscle. On the right side, however, it arises from the dorsal aspect of the second part of the subclavian artery, deep to the serratus anterior muscle. It courses upward and then arches backward above the cupula of the cervical pleura (Figs. 8-24; 8-34). Passing downward in front of the neck of the first rib, it divides into the **supreme** (highest) **intercostal** and **deep cervical** arteries.

**SUPREME INTERCOSTAL ARTERY.** The supreme or highest intercostal artery descends under the pleura anterior to the necks of the first and second ribs and anastomoses with the most superior of the intercostal arteries derived from the aorta, the one that courses in the third intercostal space (Figs. 8-24; 8-39, 8-40). As the supreme intercostal artery crosses the neck of the first rib, it lies medial to the ventral ramus of the first thoracic nerve and lateral to the cervicothoracic ganglion of the sympathetic trunk. The **first pos-**

**terior intercostal artery** branches from the supreme intercostal artery within the first intercostal space, and its distribution is the same as that of the lower posterior intercostal arteries that arise from the aorta. The supreme intercostal artery then descends, usually to become the **second posterior intercostal artery**, being joined by a branch from the highest of the aortic posterior intercostal arteries (the third). This pattern is more common on the right side, but at times the second posterior intercostal artery is derived from the aorta.

**DEEP CERVICAL ARTERY.** The deep cervical artery arises in most cases from the costocervical trunk and is analogous to the dorsal branch of an aortic posterior intercostal artery (Figs. 8-24; 8-39; 8-40). Occasionally it springs as a separate branch from the subclavian artery. Passing dorsally above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the neck of the first rib, it ascends along the dorsum of the neck, between the semispinales capitis and cervicis muscles, as high as the axis. It supplies these and adjacent muscles and anastomoses with the deep division of the descending branch of the occipital artery and with branches of the vertebral. It gives off a spinal twig, which enters the vertebral canal through the intervertebral foramen between the seventh cervical and first thoracic vertebrae.

#### **DESCENDING SCAPULAR ARTERY**

In about half the cadavers studied, a descending scapular artery branches from the third part of the subclavian artery (Fig. 8-40). When this vessel is found, its distribution is usually similar to that of the deep branch of the transverse cervical artery. The vascular pattern in this region and the course of the descending scapular artery are described with the transverse cervical artery.

## **Arteries of the Upper Limb**

The axis artery, which supplies the upper limb, continues from its origin to the elbow as a single trunk, but different portions of it are named according to the regions through which they pass. The part of the axis artery that extends from its origin to the outer bor-

der of the first rib is termed the **subclavian artery**. Beyond this point and as far as the distal border of the axilla, formed by the lower margin of the *teres major*, it is named the **axillary artery**. From the axilla to a point just beyond the elbow joint in the proximal forearm, the vessel is called the **brachial artery**; the brachial artery ends by dividing into two branches, the **radial** and **ulnar arteries**.

### THE AXILLA

The **axilla** is a cone-shaped or pyramidal region located between the upper lateral part of the chest wall and the medial aspect of the arm. Its anatomy has great relevance because through the axilla course the neurovascular structures that supply the upper extremity and because its anterior surface is relatively unprotected and vulnerable to injury. Furthermore, the axilla receives many of the *lymphatic channels* that drain the anterior thoracic wall, making it a region of strategic importance to disease processes that occur in the *mammary gland* of females.

**BOUNDARIES OF THE AXILLA.** The **apex** of the axilla is directed superiorly toward the root of the neck and corresponds to the interval between the outer border of the first rib, the superior border of the scapula, and the posterior surface of the clavicle. Through the apex pass the axillary vessels and accompanying nerves, which descend behind the clavicle from the neck. The **base** of the axilla is directed downward and laterally and is formed by the skin and fascia of the armpit. It is narrow at the arm, but broader at the chest. The thick **axillary fascia**, which helps to form the base, extends between the lower border of the *pectoralis major* muscle anteriorly and the lower border of the *latissimus dorsi* muscle posteriorly. The **anterior wall** of the axilla is formed by the *pectoralis major* and *minor* muscles, the former covering the whole of this wall and the latter only its central part. The space between the upper border of the *pectoralis minor* and the clavicle is occupied by the **clavipectoral fascia**. The **posterior wall**, which extends somewhat more caudally than the anterior wall, is formed by the *subscapularis* muscle above and the *teres major* and *latissimus dorsi* muscles below. The **medial wall** is formed by the first four

ribs with their corresponding intercostal muscles and part of the *serratus anterior*. The narrowed **lateral wall** of the axilla, where the anterior and posterior walls converge, is bounded by the *intertubercular sulcus* (bicipital groove) of the humerus, the *coracobrachialis*, and the *biceps brachii*.

**CONTENTS OF THE AXILLA.** Within the axilla are found the axillary vessels, the infraclavicular part of the brachial plexus and its branches, the lateral cutaneous branches of the intercostal nerves, and a large number of lymph nodes, together with a quantity of fat and loose areolar tissue. The axillary artery and vein, with the brachial plexus of nerves, extend obliquely through the axilla from its apex to its base and are placed much nearer the anterior wall than the posterior wall. The axillary vein lies superficial to and on the thoracic aspect of the artery and partially conceals it. In the anterior part of the axilla and in contact with the pectoral muscles are the thoracic branches of the axillary artery. Coursing downward along the lateral aspect of the chest wall, and frequently along the lateral margin of the *pectoralis minor* artery, extends the lateral thoracic artery. The subscapular vessels and nerves and the thoracodorsal nerve course along the posterior wall of the axilla, in contact with the *subscapularis* muscle. The scapular circumflex artery, which is a branch of the subscapular artery, winds around the lateral border of the *subscapularis* muscle to the dorsal aspect of the shoulder. Near the neck of the humerus, the posterior humeral circumflex vessels and the axillary nerve also curve dorsally to the shoulder. The upper medial aspect of the axilla has no large vessels, but does contain lymphatics and a few small branches from the supreme thoracic artery. There are in this region, however, the important long thoracic nerve, descending on the surface of the *serratus anterior* to which it is distributed, and the *intercostobrachial* nerve, which perforates the upper anterior aspect of the medial wall and passes across the axilla to the medial aspect of the arm.

The position and arrangement of the lymph nodes are described in the chapter on lymphatics.

### Axillary Artery

The **axillary artery** is the continuation of the subclavian, and it commences at the outer border of the first rib and ends at the

distal border of the tendon of the *teres major* muscle, where it is called the **brachial artery** (Figs. 8-42; 8-43). Its direction varies with the position of the limb: thus, the vessel is nearly straight when the arm is directed at right angles to the trunk, but concave superiorly when the arm is elevated, and convex superiorly when the arm lies by the side. At its origin the artery is quite deeply situated, but near its termination becomes superficial, being covered only by the skin and fascia. Because the *pectoralis minor* crosses the axillary artery anteriorly, for descriptive purposes it is convenient to divide the vessel into three portions: the first part lies proximal, the second part deep, and the third part distal to the *pectoralis minor*. Its branches are subject to considerable variation.

**RELATIONS OF THE FIRST PART OF THE AXILLARY ARTERY.** The first part of the axillary artery is covered *anteriorly* by the skin, the superficial fascia, the clavicular portion of the *pectoralis major*, and the clavipectoral fascia. The artery is crossed by the lateral pectoral nerve and the thoracoacromial and cephalic veins. *Posterior* to the first part of the axillary artery are the first intercostal space, the corresponding external intercostal muscle, the first and second digitations of the *serratus anterior*, the long thoracic and medial pectoral nerves, and the medial cord of the brachial plexus. *Laterally*, the vessel is in relation to the lateral and posterior cords of the brachial plexus, from which it is separated by a little areolar tissue. *Medially*, the axillary vein closely overlaps the artery. The first part of the axillary artery is enclosed, together with the axillary vein and brachial plexus, in the fibrous **axillary sheath**, which is continuous above with the prevertebral layer of the deep cervical fascia.

**RELATIONS OF THE SECOND PART OF THE AXILLARY ARTERY.** The second part of the axillary artery is covered *anteriorly* by the skin, the superficial and deep fasciae, the *pectoralis major* muscle, and, immediately anterior to the artery, the *pectoralis minor* muscle. *Dorsal* to the second part of the artery are the posterior cord of the brachial plexus and some areolar tissue, both of which intervene between the vessel and the subscapularis muscle. *Medially*, the axillary vein is separated from the artery by the medial cord of the brachial plexus and the medial pectoral nerve. *Laterally* is found the lateral cord of the brachial plexus. The cords of the brachial plexus thus surround the artery on three sides and separate it from direct contact with the vein and adjacent muscles.

**RELATIONS OF THE THIRD PART OF THE AXILLARY ARTERY.** The third part of the axillary artery extends from the lateral border of the *pectoralis minor* to the distal border of the tendon of the *teres major*. Its proximal portion is covered *anteriorly* by the *pectoralis major* muscle, its distal portion by only the in-

tegument and fascia. *Posteriorly* are found the subscapularis muscle and the tendons of the *latissimus dorsi* and *teres major*. On its *lateral aspect* is the coracobrachialis muscle and on its *medial* or *thoracic aspect* the axillary vein. The *nerves of the brachial plexus* bear the following relations to the third part of the artery: on the *lateral aspect* are the lateral root and trunk of the median nerve, and the musculocutaneous nerve for a short distance. On the *medial aspect* (between the axillary vein and artery) are found the ulnar nerve and (to the medial aspect of the vein) the medial brachial cutaneous nerve. *Anteriorly* are the medial root of the median nerve and the medial antebrachial cutaneous nerve, and posteriorly the radial and axillary nerves, the latter extending only as far as the distal border of the subscapularis muscle.

**COLLATERAL CIRCULATION AFTER LIGATURE OF THE AXILLARY ARTERY.** If the axillary artery is tied proximal to the origin of the thoracoacromial artery, the collateral circulation achieved is the same as that which results from ligature of the third part of the subclavian. If the ligature is made more distally between the thoracoacromial and the subscapular, the latter vessel, by its free anastomosis with the supra-scapular and transverse cervical branches of the subclavian, becomes the chief agent in carrying on the circulation. If the lateral thoracic artery is distal to the ligature, it materially contributes to the circulation by its anastomoses with the intercostal and internal thoracic arteries. A ligature made distal to the origin of the subscapular artery is probably also distal to the origins of the two humeral circumflex arteries, in which case the chief vessels providing blood to more distal structures in the arm are the subscapular and the two humeral circumflex arteries anastomosing with branches of the deep brachial artery.

### Branches of the Axillary Artery

Although quite variable in their pattern, usually one branch is derived from the first part of the axillary artery, two from the second, and three from the third. They are:

#### First Part:

Supreme thoracic

#### Second Part:

Thoracoacromial

Lateral thoracic

#### Third Part:

Subscapular

Posterior humeral circumflex

Anterior humeral circumflex

### SUPREME THORACIC ARTERY

The supreme thoracic artery is a small vessel which usually arises from the axillary artery just below the clavicle, but it may

branch from the thoracoacromial artery or may be absent. It passes medially, generally behind the axillary vein, to the side of the chest in the first intercostal space (Figs. 8-42; 8-43). Coursing between the pectoralis minor and major, the supreme thoracic artery supplies branches to these muscles, and to the wall of the thorax, anastomosing with the internal thoracic and upper one or two intercostal arteries.

#### THORACOACROMIAL ARTERY

The thoracoacromial artery is a short trunk that arises anteriorly from the axillary artery, its origin being generally overlapped by the upper (or medial) edge of the pectoralis minor (Figs. 8-35; 8-42; 8-43). At the border of this muscle, the vessel pierces the clavipectoral fascia and divides into four branches: pectoral, acromial, clavicular, and deltoid.

**PECTORAL BRANCHES.** The pectoral branches of the thoracoacromial artery descend between the two pectoral muscles and are distributed to them and to the breast, anastomosing with the intercostal branches

of the internal thoracic and with the lateral thoracic artery (Fig. 8-33).

**ACROMIAL BRANCH.** The acromial branch courses laterally, superficial to the coracoid process and deep to the deltoid muscle to which it gives branches (Figs. 8-33; 8-44). It then pierces that muscle and ends on the acromion in an arterial network, called the **acromial rete**, formed by branches from the suprascapular, the deltoid branch of the thoracoacromial artery, and the posterior humeral circumflex artery.

**CLAVICULAR BRANCH.** The clavicular branch of the thoracoacromial artery courses upward and medially beneath the clavicle to the sternoclavicular joint. It supplies this articulation and the subclavius muscle and anastomoses with the suprascapular artery.

**DELTOID BRANCH.** The deltoid branch frequently arises with the acromial branch and crosses laterally, superficial to the pectoralis minor (Fig. 8-33). It courses in the deltopectoral groove with the cephalic vein, passing between the pectoralis major and deltoid, and supplying branches to both muscles.

**FIG. 8-42.** The axillary artery and its branches. This vascular pattern shows all six branches of the artery derived from the main stem.

**LATERAL THORACIC ARTERY**

The lateral thoracic artery (Figs. 8-42; 8-43) follows the lateral or lower border of the pectoralis minor to the side of the chest. It supplies the serratus anterior and both pectoral muscles and sends branches across the axilla to the axillary lymph nodes and subscapularis muscle. The lateral thoracic artery anastomoses with the internal thoracic, subscapular, and intercostal arteries, and with the pectoral branches of the thoracoacromial. The lateral thoracic artery is often (60%) a branch either of the thoracoacromial artery or of the subscapular artery. It comes directly from the axillary only in about 30% of cases.

**LATERAL MAMMARY BRANCHES.** In the female, the lateral mammary branches (sometimes called the external mammary branches) can be of considerable size. They turn around the free lateral margin of the pectoralis major and supply the breast.

**SUBSCAPULAR ARTERY**

The subscapular artery is usually the largest branch of the axillary artery and it arises at the distal border of the subscapularis muscle. Lying on the anterior surface of the subscapularis muscle, it descends under cover of the latissimus dorsi. After a short course of about 4 cm, the subscapular artery divides into the circumflex scapular and thoracodorsal arteries (Figs. 8-30; 8-42; 8-43).

**CIRCUMFLEX SCAPULAR ARTERY.** The circumflex scapular artery is generally larger than the thoracodorsal artery. It curves around the lateral border of the scapula, traversing the **triangular space** bordered below by the teres major, above by the subscapularis, and laterally by the long head of the triceps. The vessel then enters the infraspinous fossa between the teres minor and the scapula, remaining close to the bone (Fig. 8-44). It supplies branches to the infraspinatus and anastomoses with the suprascapular

**Fig. 8-43.** The axillary artery and its branches. Note that in this vascular pattern, the lateral thoracic artery is derived from the thoracoacromial artery rather than directly from the axillary, and a lateral thoracic branch also comes from the subscapular artery. This pattern is seen in about 33% of cases.

artery and the deep branch of the transverse cervical artery (which in some cadavers is the descending branch of the descending scapular artery). In the triangular space, the circumflex scapular artery gives a branch to the subscapularis muscle. Another large branch continues along the lateral border of the scapula between the teres major and minor, supplying these muscles as well as the long head of the triceps and the deltoid. Finally, it anastomoses with the deep branch of the transverse cervical artery (or descending branch of the descending scapular) at the inferior angle of the scapula.

**THORACODORSAL ARTERY.** The thoracodorsal artery (Figs. 8-33; 8-43) is the continuation inferiorly of the subscapular artery through the axilla along the anterior border of the latissimus dorsi muscle. The vessel courses with the thoracodorsal nerve; it gives branches to the subscapularis and is the principal supply to the latissimus. It anastomoses with the circumflex scapular artery and the deep branch of the transverse cervical artery (or descending branch of the descending scapular artery). One or two sizable branches cross the axilla to supply the serratus anterior and intercostal muscles, anastomosing with the intercostal, lateral thoracic, and thoracoacromial arteries. When the lateral thoracic artery is small or

lacking, a branch of the thoracodorsal may take its place.

#### POSTERIOR HUMERAL CIRCUMFLEX ARTERY

The posterior humeral circumflex artery arises from the axillary artery at the distal border of the subscapularis muscle (Figs. 8-42 to 8-44). It curves dorsally with the axillary nerve through the **quadrangular space** bounded by the subscapularis and teres minor muscles above, the teres major below, the long head of the triceps brachii medially, and the surgical neck of the humerus laterally (Fig. 8-44). The artery winds around the neck of the humerus and is distributed to the deltoid muscle and the shoulder joint, anastomosing with the anterior humeral circumflex and deep brachial arteries.

#### ANTERIOR HUMERAL CIRCUMFLEX ARTERY

The anterior humeral circumflex artery is considerably smaller than the posterior humeral circumflex, and it arises from the lateral aspect of the axillary artery near the lower border of the subscapularis muscle and opposite the posterior humeral circumflex artery (Figs. 8-42 to 8-44). It may arise in

FIG. 8-44. The anastomoses on the posterior aspect of the shoulder.

common with the posterior humeral circumflex or be represented by three or four very small branches. The vessel runs horizontally beneath the coracobrachialis muscle and short head of the biceps brachii, anterior to the neck of the humerus. As it reaches the intertubercular sulcus, it gives off a branch that ascends in the sulcus to supply the head of the humerus and the shoulder joint. The main stem of the artery then continues laterally, deep to the long head of the biceps bra-

chii and the deltoid, to anastomose with the posterior humeral circumflex artery.

### **Brachial Artery**

The **brachial artery** is the continuation of the axillary artery and originates at the lower margin of the tendon of the teres major muscle. It passes down the arm and ends about 1 cm distal to the bend of the elbow, where it divides into the **radial** and **ulnar arteries** (Figs. 8-45; 8-46). At first the

**FIG. 8-45.** The major arteries of the upper extremity. The branching pattern shown in this diagram is the one most commonly observed.

brachial artery lies medial to the humerus, but as it descends, it gradually curves to the front of the arm, and at the antecubital fossa anterior to the elbow joint, it lies midway between its two epicondyles.

**RELATIONS.** The brachial artery is superficial throughout its entire course, being covered *anteriorly* by the skin and the superficial and deep fasciae. The bicipital aponeurosis, which extends from the biceps brachii muscle, lies anterior to the artery in front of the elbow, separating it from the median cubital vein. The median nerve crosses the brachial artery from lateral to medial, opposite the insertion of the coracobrachialis muscle (Fig. 8-46). *Posteriorly*, the brachial artery is separated from the long head of the triceps brachii by the radial nerve and the deep brachial artery. It then lies successively on the medial head of the triceps brachii, on the insertion of the coracobrachialis, and finally on the brachialis muscle. *Laterally*, the brachial artery is in relation more proximally in the arm with the median nerve and the coracobrachialis muscle and more distally with the biceps brachii, the two muscles overlapping the artery to a considerable extent. *Medially*, the proximal half of the brachial artery is in relation with the medial antebrachial cutaneous and ulnar nerves, while medial to the distal half of the artery is found the median nerve. The basilic vein also lies to its medial side, but is separated from it in the distal part of the arm by the deep fascia. The artery is accompanied by two venae comitantes, which lie in close contact to it and are interconnected at intervals by short transverse branches.

**CUBITAL FOSSA.** On the anterior aspect of the bend at the elbow, the brachial artery sinks deeply into a triangular interval, the **cubital fossa**. The base of the triangle is directed proximally and is represented by a line connecting the two epicondyles of the humerus. The sides of the triangle are formed by the medial edge of the brachioradialis muscle and the lateral margin of the pronator teres. The apex of the triangle is directed inferiorly at the point where the two muscles meet. The floor of the cubital fossa is formed by the brachialis and supinator muscles. This fossa contains the tendon of the biceps brachii muscle, the brachial artery with its accompanying veins, the stems of the radial and ulnar arteries, and a part of the median nerve.

The brachial artery occupies the middle of the cubital fossa and divides opposite the neck of the radius into the radial and ulnar arteries. It is covered *anteriorly* by the skin, superficial fascia, and median cubital vein,

the last being separated from the artery by the bicipital aponeurosis. *Posteriorly*, it is the brachialis muscle that separates the artery from the elbow joint. The median nerve lies close to the *medial aspect* of the artery in the upper part of the fossa, but is separated from it more distally by the ulnar head of the pronator teres. The tendon of the biceps brachii lies to the *lateral aspect* of the artery.

The radial nerve normally lies just outside the fossa, between the supinator and the brachioradialis muscles, but may be exposed by entering through the fossa and deflecting the brachioradialis laterally.

**VARIATIONS OF THE BRACHIAL ARTERY.** The brachial artery, accompanied by the median nerve, may leave the medial border of the biceps brachii and descend toward the medial epicondyle of the humerus. In such cases it usually passes behind a *supracondylar process* of the humerus, from which a fibrous arch is thrown over the vessel. It then runs beneath or through the substance of the pronator teres to the bend of the elbow. This variation bears considerable analogy with the normal condition of the artery in some of the carnivores.

A frequent variation is the presence of a **superficial brachial artery**, which may continue into the forearm to form a **superficial antebrachial artery** or may rejoin the brachial distally. Frequently the brachial artery divides at a higher level than usual, and the three vessels concerned in this high division are the radial, ulnar, and common interosseous arteries. Most frequently, the radial artery branches high in the arm, while the other limb of the bifurcation consists of the ulnar and common interosseous arteries. In some instances, the ulnar arises above the ordinary level, and the radial and common interosseous form the other limb of the division. Occasionally the common interosseous arises at a higher level (see Fig. 8-12).

Sometimes long, slender vessels called **vasa aberrantia** connect the brachial or axillary artery with one of the arteries of the forearm, or with branches from them. Such vessels usually join the radial artery.

**COLLATERAL CIRCULATION.** After the application of a ligature to the brachial artery in the *upper third of the arm*, blood can circulate through branches from the anterior and posterior humeral circumflex and subscapular arteries, which anastomose with ascending branches from the deep brachial artery. If the main stem of the brachial artery is tied *below* the origin of the deep brachial artery and the superior ulnar collateral, circulation is maintained by branches of these two vessels, which anastomose with the inferior ulnar collateral, the radial and ulnar recurrent arteries, and the posterior interosseous artery.

**Fig. 8-46.** The right brachial artery and some of its branches.

**CLINICAL NOTE.** To control excessive bleeding, the brachial artery should be compressed laterally against the humerus in the upper third of the arm, laterally and backward in the middle third, and directly backward in the lower third as the vessel courses anterior to the humerus in this region.

### Branches of the Brachial Artery

As it descends in the arm, the brachial artery and its branches supply the humerus, muscles, and other tissues of the region, as well as participate in the anastomosis

around the elbow joint. The branches of the brachial artery are:

- Deep brachial
- Principal nutrient artery of humerus
- Superior ulnar collateral
- Inferior ulnar collateral
- Muscular

### DEEP BRACHIAL ARTERY

The deep brachial artery (profund brachii) is the largest branch of the brachial artery. It arises from the medial and posterior

part of the main stem, just distal to the lower border of the *teres major* muscle (Figs. 8-45; 8-46). Initially, the deep brachial artery passes backward into the arm between the long and lateral heads of the *triceps brachii*. It then accompanies the radial nerve in the spiral groove between the lateral and medial heads of the *triceps*, on the posterior aspect of the humerus. The vessel terminates by dividing into the radial collateral and middle collateral arteries. The deep brachial artery has four named branches in addition to muscular vessels:

Deltoid (ascending)  
Radial collateral  
Middle collateral  
Nutrient

**DELTOID (ASCENDING) BRANCH.** The deltoid branch of the deep brachial artery ascends between the long and lateral heads of the *triceps brachii* muscle. It anastomoses with a descending branch of the posterior humeral circumflex artery and helps to supply the *brachialis* and *deltoid* muscles.

**RADIAL COLLATERAL ARTERY.** The radial collateral artery, which is frequently described as the terminal portion of the deep brachial

artery, continues into the forearm with the radial nerve. It lies deep to the lateral head of the *triceps* until it reaches the lateral supracondylar ridge of the humerus. At this site, it pierces the lateral intermuscular septum, descends between the *brachioradialis* and the *brachialis* muscles to the palmar aspect of the lateral epicondyle, and ends by anastomosing with the radial recurrent artery. Just before the radial collateral artery pierces the intermuscular septum, it gives off a branch that descends to the posterior aspect of the lateral epicondyle and there joins the anastomosis around the elbow.

**MIDDLE COLLATERAL ARTERY.** The middle collateral artery is usually larger than the radial collateral branch (Fig. 8-47). It enters the substance of the long and medial heads of the *triceps* and descends along the posterior aspect of the humerus to the elbow, where it anastomoses with the *interosseous recurrent* and joins into the anastomosis around the elbow.

**NUTRIENT BRANCH.** A nutrient branch, which usually is accessory to the principal nutrient artery from the *brachial*, enters a nutrient canal of the humerus posterior to the *deltoid tuberosity*. It may be absent.

FIG. 8-47. Diagram of the anastomosis around the elbow joint.

### PRINCIPAL NUTRIENT ARTERY OF HUMERUS

The main or principal nutrient artery of the humerus arises from the brachial about at the middle of the arm and enters a nutrient canal near the insertion of the coracobrachialis muscle.

### SUPERIOR ULNAR COLLATERAL ARTERY

The superior ulnar collateral artery is a long and slender vessel that arises from the brachial a little below the middle of the arm (Figs. 8-45 to 8-47). It frequently springs from the proximal part of the deep brachial artery. It pierces the medial intermuscular septum and descends, with the ulnar nerve, on the surface of the medial head of the triceps brachii to the space between the medial epicondyle and olecranon. The vessel ends deep to the flexor carpi ulnaris by anastomosing with the posterior ulnar recurrent and inferior ulnar collateral arteries. It sometimes sends a branch anterior to the medial epicondyle, to anastomose with the anterior ulnar recurrent artery.

### INFERIOR ULNAR COLLATERAL ARTERY

The inferior ulnar collateral artery arises about 5 cm above the elbow (Figs. 8-45 to 8-47). Initially, it passes medially upon the brachialis, and piercing the medial intermuscular septum, it then winds around the dorsum of the humerus between the triceps brachii and the bone. By its junction with the middle collateral branch of the deep brachial artery, it forms an arch just above the olecranon fossa. As the vessel lies on the brachialis, it gives off branches that ascend to anastomose with the superior ulnar collateral, and others that descend in front of the medial epicondyle to anastomose with the anterior ulnar recurrent. Behind the medial epicondyle a branch anastomoses with the superior ulnar collateral and posterior ulnar recurrent arteries.

### MUSCULAR BRANCHES

The brachial artery gives off three or four muscular branches which are distributed to the coracobrachialis, biceps brachii, and brachialis muscles.

### ANASTOMOSIS AROUND THE ELBOW JOINT.

The vessels contributing to this anastomosis may be conveniently divided into those anterior to and those posterior to the medial and lateral epicondyles of the humerus (Fig. 8-47). The branches anastomosing *anterior to the medial epicondyle* are the anterior branch of the inferior ulnar collateral, the anterior ulnar recurrent, and the anterior branch of the superior ulnar collateral. Those *posterior to the medial epicondyle* are the inferior ulnar collateral, the posterior ulnar recurrent, and the posterior branch of the superior ulnar collateral. The branches anastomosing *anterior to the lateral epicondyle* are the radial recurrent and the radial collateral branch of the deep brachial artery. Those situated *posterior to the lateral epicondyle* are the inferior ulnar collateral, the interosseous recurrent, and the middle collateral branch of the deep brachial artery. There is also a transverse arch of anastomosis, which crosses the posterior aspect of the arm just proximal to the olecranon, formed by the interosseous recurrent joining with the inferior ulnar collateral and posterior ulnar recurrent (Fig. 8-47).

### Ulnar Artery

The **ulnar artery** is the larger of the two terminal branches of the brachial and, like the radial artery, it begins about 1 cm distal to the bend of the elbow (Figs. 8-48; 8-50 to 8-52). Passing obliquely downward and medially, it reaches the ulnar side of the forearm at a point about midway between the elbow and the wrist. It then runs along the ulnar border to the wrist, crosses the flexor retinaculum on the radial side of the ulnar nerve and pisiform bone, and, immediately beyond this bone, becomes the **superficial palmar arch**.

**RELATIONS OF THE ULNAR ARTERY.** In the **proximal half of the forearm**, the ulnar artery is deeply seated, being covered by the pronator teres, flexor carpi radialis, palmaris longus, and flexor digitorum superficialis muscles. It lies upon the brachialis and flexor digitorum profundus muscles (Fig. 8-51). For about 2.5 cm from its commencement at the elbow, the ulnar artery courses lateral to the median nerve, and then the median nerve crosses anterior to the artery but is separated from it by the ulnar half of the pronator teres muscle. In the **distal half of the forearm**, the ulnar artery lies upon the flexor digitorum profundus, being covered by the skin and the superficial and deep fasciae, and being placed between

the flexor carpi ulnaris and flexor digitorum superficialis (Figs. 8-48; 8-51). The artery is accompanied by two venae comitantes, and it is overlapped in its middle third by the flexor carpi ulnaris. The ulnar nerve lies on the medial side of the distal two-thirds of the artery, and the palmar cutaneous branch of

the ulnar nerve descends on the distal part of the vessel to the palm of the hand.

**At the wrist** the ulnar artery lies on the flexor retinaculum and is covered by skin, the fasciae, and the palmaris brevis (Figs. 8-48; 8-50 to 8-52). On its medial side is the pisiform bone and, slightly dorsal to the artery, the ulnar nerve.

**VARIATIONS.** The ulnar artery varies in its origin in somewhat less than 10% of cases. It may arise about 5 to 7 cm below the elbow, but more frequently higher. Variations in the position of this vessel are more common than in the radial. When its origin from the brachial is normal, the course of the vessel is rarely changed. When it arises higher up, its course is almost invariably superficial to the flexor muscles in the forearm, lying commonly beneath the deep fascia, more rarely between the fascia and skin. In a few instances, its position has been reported to be subcutaneous in the upper part of the forearm and beneath the deep fascia in the lower part.

### Branches of the Ulnar Artery

The branches of the ulnar artery may be arranged into three groups, like those of the radial artery.

In the forearm:

- Anterior ulnar recurrent
- Posterior ulnar recurrent
- Common interosseous
- Anterior interosseous
- Posterior interosseous

Muscular

At the wrist:

- Palmar carpal
- Dorsal carpal

In the hand:

- Deep palmar
- Superficial palmar arch
- Common palmar digital

**FIG. 8-48.** The ulnar and radial arteries and the superficial palmar arch.

### ANTERIOR ULNAR RECURRENT

The anterior ulnar recurrent artery arises immediately below the elbow joint from the medial aspect of the ulnar artery (Fig. 8-51). It courses upward between the brachialis muscle and the pronator teres, supplying these muscles and, in front of the medial epicondyle, anastomoses with the inferior ulnar collateral artery.

### POSTERIOR ULNAR RECURRENT

The posterior ulnar recurrent artery is much larger and arises somewhat more distally than the anterior ulnar recurrent, but

also from the medial side of the ulnar artery (Figs. 8-49; 8-51). It passes medially and backward between the flexor digitorum superficialis and flexor digitorum profundus, and then it ascends behind the medial epicondyle of the humerus. Between this process and the olecranon it lies beneath the flexor carpi ulnaris and ascends, together with the ulnar nerve, between the two heads of that muscle. The posterior ulnar recurrent artery, which supplies the neighboring muscles and the elbow joint, anastomoses with the superior and inferior ulnar collateral and the interosseous recurrent arteries.

#### COMMON INTEROSSEOUS ARTERY

The common interosseous artery is a short, thick vessel, only one centimeter long, which arises from the lateral and posterior aspect of the ulnar artery, immediately distal to the tuberosity of the radius (Fig. 8-51). The vessel passes dorsal to the upper border of the interosseous membrane, where it divides into two branches, the anterior and posterior interosseous arteries.

**ANTERIOR INTEROSSEOUS ARTERY.** The anterior interosseous artery passes down the forearm on the anterior surface of the interosseous membrane (Figs. 8-49; 8-51). It is accompanied by the palmar interosseous branch of the median nerve and is overlapped by the contiguous margins of the flexor digitorum profundus and flexor pollicis longus, giving off **muscular branches** and **nutrient arteries** to the radius and ulna. At the proximal border of the pronator quadratus it gives off a small branch that descends dorsal to the pronator to reach the *palmar carpal network* (Fig. 8-51), and then the anterior interosseous artery pierces the interosseous membrane to enter the posterior compartment of the forearm, where it anastomoses with the dorsal interosseous artery (Fig. 8-49). On the posterior aspect of the interosseous membrane in the lower forearm, the anterior interosseous artery descends in company with the terminal portion of the posterior interosseous nerve (from the deep branch of the radial nerve) to the dorsum of the wrist to join the *dorsal carpal network*.

The **median artery** is a long, slender branch that arises from the proximal part of the anterior interosseous artery. It passes forward to the median nerve, which it accompanies and supplies in its course down

the forearm. This artery is sometimes much enlarged, and when so, it courses with the median nerve into the palm of the hand and enters into the formation of the superficial palmar arch.

**POSTERIOR INTEROSSEOUS ARTERY.** The posterior interosseous artery, smaller than the anterior, arises from the common interosseous artery and passes dorsally either over or between the oblique cord and the proximal border of the interosseous membrane (Figs. 8-49; 8-51). It appears between the contiguous borders of the supinator and the abductor pollicis longus and descends in the posterior compartment of the forearm between the superficial and deep layers of muscles, sending branches to both groups. Coursing along the surface of the abductor pollicis longus and the extensor pollicis brevis, it is accompanied by the posterior interosseous nerve, which is derived from the deep branch of the radial nerve. In the distal forearm, it anastomoses with terminal branches of the anterior interosseous artery and with the *dorsal carpal network*.

The **interosseous recurrent artery** branches from the posterior interosseous artery near its origin, or at times it may arise directly from the common interosseous artery (Fig. 8-49). It ascends on or through the fibers of the supinator to the interval between the lateral epicondyle and olecranon, but deep to the anconeus muscle. Here it anastomoses with the middle collateral branch of the deep brachial artery, the posterior ulnar recurrent artery, and the inferior ulnar collateral artery.

#### MUSCULAR BRANCHES

Many muscular branches arise from the ulnar artery in the forearm (Fig. 8-51). These supply the superficial and deep flexors of the fingers and muscles on the ulnar aspect of the forearm, including the flexors carpi radialis and ulnaris, as well as the pronator teres.

#### PALMAR CARPAL BRANCH

The palmar carpal branch is a small vessel that arises from the ulnar artery opposite the carpal bones. It crosses the palmar aspect of the wrist joint, deep to the tendons of the flexor digitorum profundus (Fig. 8-51), and anastomoses with the corresponding palmar carpal branch of the radial artery.

Fig. 8-49. Arteries on the posterior aspect of the forearm, wrist, and hand.

#### DORSAL CARPAL BRANCH

The dorsal carpal branch of the ulnar artery arises immediately above the pisiform bone and winds dorsally beneath the tendon of the flexor carpi ulnaris (Fig. 8-49). It then passes across the dorsal surface of the wrist beneath the extensor tendons, to anastomose with the corresponding dorsal carpal branch of the radial artery. Just beyond its origin, it gives off a small branch that courses along

the ulnar aspect of the fifth metacarpal bone, supplying the ulnar aspect of the dorsal surface of the little finger.

#### DEEP PALMAR BRANCH

The deep palmar branch arises from the ulnar artery at the level of the flexor retinaculum (Figs. 8-48; 8-50 to 8-52). It courses medially between the abductor digiti minimi and flexor digiti minimi brevis and through

**FIG. 8-50.** The superficial palmar arch and the common and proper digital arteries of the right hand. Note that the ulnar artery is the principal contributor to the superficial palmar arch.

the origin of the opponens digiti minimi, all of which are muscles of the hypothenar eminence. The vessel then curves laterally into the palm, accompanied by the deep branch of the radial nerve, to anastomose with the radial artery and complete the **deep palmar arch**.

#### **SUPERFICIAL PALMAR ARCH**

The superficial palmar arch is formed primarily by the deep palmar branch of the ulnar artery and is usually completed by a

branch that comes from the radial artery (Figs. 8-48; 8-50). Most frequently this is the superficial palmar branch of the radial, but it may be the radial index artery or the princeps pollicis artery. More rarely, the median artery, which is a branch of the anterior interosseous artery, descends to help form the arch. The superficial palmar arch curves across the palm with its convexity oriented distally. It is covered by the skin, the palmaris brevis, and the palmar aponeurosis, and it lies upon the flexor retinaculum, the flexor digiti minimi brevis and opponens

digiti minimi, the tendons of the flexor digitorum superficialis, the lumbrical muscles, and branches of the median and ulnar nerves. The superficial palmar arch gives rise to three common palmar digital arteries.

**COMMON PALMAR DIGITAL ARTERIES.** Three common palmar digital arteries arise from the convexity of the superficial palmar arch and proceed distally on the second, third, and fourth lumbrical muscles (Figs. 8-48; 8-50 to 8-52). Each is joined by the corresponding palmar metacarpal artery from the deep palmar arch, and then divides into a pair of **proper palmar digital arteries** (Figs. 8-50 to 8-52). These latter vessels course along the contiguous sides of the index, middle, ring, and little fingers dorsal to the corresponding digital nerves. They anastomose freely in the subcutaneous tissue of the finger tips and by smaller branches near the interphalangeal joints. Each gives off two dorsal branches, which anastomose with the dorsal digital arteries, and supply the soft parts on the dorsum of the middle and distal phalanges, including the matrix of the fingernail. The proper palmar digital artery for the ulnar aspect of the little finger springs from the ulnar artery under cover of the palmaris brevis.

### Radial Artery

Due to its direction, the **radial artery** appears to be the direct continuation of the brachial trunk, but it is smaller in caliber than the ulnar artery, which is the other terminal branch of the brachial artery (Figs. 8-45; 8-48; 8-51). It originates at the bifurcation of the brachial artery opposite the neck of the radius, about 1 cm below the bend of the elbow, and passes along the radial aspect of the forearm to the wrist. It then winds around the lateral aspect of the carpus to the dorsum of the wrist, deep to the tendons of the abductor pollicis longus and the extensors pollicis longus and brevis, reaching the proximal end of a space between the metacarpal bones of the thumb and index finger. Finally it passes between the two heads of the first dorsal interosseous muscle into the palm of the hand, joining the deep palmar branch of the ulnar artery to form the deep palmar arch. Hence, the radial artery has three parts, one part in the forearm, another at the wrist, and a third part in the hand.

**RELATIONS OF THE RADIAL ARTERY.** The radial artery in the forearm extends from the neck of the radius to the anterior aspect of its styloid process, being placed to the medial aspect of the radial shaft proximally and anterior to the bone distally (Figs. 8-48; 8-51). The upper part of the artery is overlapped by the fleshy belly of the brachioradialis muscle, while the rest of the artery is superficial, being covered only by skin and the superficial and deep fasciae. In its course through the forearm, the radial artery lies first upon the biceps tendon, and then successively on the supinator muscle, the pronator teres muscle, the radial origin of the flexor digitorum superficialis muscle, the flexor pollicis longus muscle, the pronator quadratus muscle, and the distal end of the radius. In the proximal third of its course, it lies between the brachioradialis and the pronator teres muscles; in the distal third of its course it lies between the brachioradialis and flexor carpi radialis muscles. The superficial branch of the radial nerve is close to the lateral aspect of the artery in the middle third of its course, and some filaments of the lateral antebrachial cutaneous nerve run along the lower part of the artery as it winds around the wrist. The vessel is accompanied by a pair of venae comitantes throughout its whole course. Distally the radial artery lies on the lower anterior aspect of the radius and, being very superficial, is an *ideal site for taking the pulse*.

**At the wrist,** the radial artery reaches the dorsum of the carpus by passing between the radial collateral ligament of the wrist and the tendons of the abductor pollicis longus and extensor pollicis brevis muscles (Fig. 8-49). It then descends on the scaphoid and trapezium, and before disappearing between the heads of the first dorsal interosseous muscle, it is crossed by the tendon of the extensor pollicis longus. In the interval between the two extensors of the thumb, sometimes called the "anatomical snuff box," the radial artery is crossed by the dorsal digital nerves as they pass to the thumb and index finger; these nerves are derived from the superficial branch of the radial nerve.

**In the hand,** the radial artery passes through the proximal end of the first interosseous space, between the heads of the first dorsal interosseous muscle (Figs. 8-50; 8-52). It then crosses the palm transversely between the oblique and transverse heads of the adductor pollicis muscle. The vessel then pierces the transverse head and reaches the base of the metacarpal bone of the little finger, where it anastomoses with the deep palmar branch from the ulnar artery, completing the **deep palmar arch** (Figs. 8-51; 8-52).

**VARIATIONS.** The origin of the radial artery is higher than usual in about 12% of cases. In the forearm it deviates less frequently from its normal position than does the ulnar artery. It has been observed lying on the deep fascia of the forearm, instead of beneath it. It has also been seen on the surface of the brachioradialis instead of deep to its medial bor-

Fig. 8-51. The radial and ulnar arteries in the deep forearm and the deep palmar arch in the hand.

der. In its course around the wrist, the radial artery has been seen lying on the extensor tendons of the thumb instead of beneath them. The presence of a large **median artery** may replace the radial in the formation of the palmar arches.

#### Branches of the Radial Artery

The branches of the radial artery may be divided into three groups, which correspond

to the three regions in which the vessel is situated.

In the forearm:

Radial recurrent  
Muscular  
Palmar carpal  
Superficial palmar

At the wrist:

Dorsal carpal

**Fig. 8-52.** The deep palmar arch and princeps pollicis artery. Note that the radial artery is the principal contributor to this arch, but that it anastomoses with the deep palmar branch of the ulnar artery.

First dorsal metacarpal  
In the hand:

Deep palmar arch  
Palmar metacarpal  
Perforating  
Recurrent

#### RADIAL RECURRENT ARTERY

The radial recurrent artery arises immediately below the elbow (Figs. 8-48; 8-51). It ascends between the branches of the radial nerve, lying on the supinator muscle and then between the brachioradialis and brach-

ialis muscles. The vessel supplies these muscles and the elbow joint and anastomoses with the radial collateral branch of the deep brachial artery.

#### MUSCULAR BRANCHES

The radial artery sends muscular branches to the brachioradialis and pronator teres muscles, as well as to other muscles on the radial aspect of the forearm.

#### PALMAR CARPAL BRANCH

The palmar carpal branch of the radial artery (Figs. 8-51; 8-52) is a small vessel that arises near the distal border of the pronator

quadratus and, running across the palmar aspect of the wrist, anastomoses with the palmar carpal branch of the ulnar artery. This anastomosis is joined by a branch from the anterior interosseous artery proximally and by recurrent branches from the deep palmar arch distally, thus forming a **palmar carpal network**, which supplies the articulations of the wrist and the carpal bones (Fig. 8-52).

#### SUPERFICIAL PALMAR BRANCH

The superficial palmar branch arises from the radial artery just above the wrist, where the radial artery is about to wind laterally around the carpus (Figs. 8-48; 8-50 to 8-52). It passes through, but occasionally over, the muscles of the thenar eminence, which it supplies. The vessel then anastomoses with the terminal portion of the ulnar artery, completing the **superficial palmar arch** (Figs. 8-48; 8-50). The superficial palmar branch of the radial artery varies considerably in size. Frequently it is very small and ends in the muscles of the thumb, but sometimes it is as large as the continuation of the radial.

#### DORSAL CARPAL BRANCH

The dorsal carpal branch of the radial artery is a small vessel that arises deep to the extensor tendons of the thumb. Crossing the carpus transversely toward the medial border of the hand, it anastomoses with the dorsal carpal branch of the ulnar artery and with terminal branches of the anterior and posterior interosseous arteries to form a **dorsal carpal network**. From this network are given off three slender **dorsal metacarpal arteries**, which run distally on the second, third, and fourth dorsal interosseous muscles (Fig. 8-49). The metacarpal arteries bifurcate into **dorsal digital branches**, which then supply the adjacent sides of the index, middle, ring, and little fingers. The dorsal digital vessels anastomose with the proper palmar digital branches of the superficial palmar arch. Near their origins the dorsal metacarpal arteries anastomose with the deep palmar arch by the **proximal perforating arteries**, and near their points of bifurcation, they also anastomose with the common

palmar digital vessels of the superficial palmar arch by the **distal perforating arteries**.

#### FIRST DORSAL METACARPAL ARTERY

The first dorsal metacarpal artery arises just before the radial artery passes between the two heads of the first dorsal interosseous muscle (Fig. 8-49). It divides almost immediately into two branches, which supply the adjacent sides of the thumb and index finger. The radial aspect of the thumb receives a branch directly from the radial artery.

#### PRINCEPS POLICIS ARTERY

The princeps pollicis artery arises from the radial artery as it turns medially toward the deep part of the palm (Figs. 8-48; 8-51; 8-52). It descends between the first dorsal interosseous muscle and the oblique head of the adductor pollicis, along the ulnar aspect of the metacarpal bone of the thumb to the base of the first phalanx. Here the princeps pollicis artery lies beneath the tendon of the flexor pollicis longus and divides into two branches. These make their appearance between the medial and lateral insertions of the oblique head of the adductor pollicis muscle and run along the sides of the thumb (Figs. 8-50; 8-52). On the palmar surface of the distal phalanx, they form an arch from which branches are distributed to the skin and subcutaneous tissue of the thumb.

#### RADIAL INDEX ARTERY

The radial index artery (*arteria radialis indicis*) arises from the radial artery close to the princeps pollicis artery, between the first dorsal interosseous muscle and the transverse head of the adductor pollicis muscle (Figs. 8-48; 8-50; 8-51). It courses along the radial aspect of the index finger to its extremity, where it anastomoses with the proper digital artery supplying the ulnar aspect of the finger. At the distal border of the transverse head of the adductor pollicis, this vessel anastomoses with the princeps pollicis and gives a communicating branch to the superficial palmar arch. The princeps pollicis and radial index arteries may spring from a common trunk, which is then called the **first palmar metacarpal artery**.

**DEEP PALMAR ARCH**

The deep palmar arch is the terminal part of the radial artery and it anastomoses with the deep palmar branch of the ulnar artery (Figs. 8-51; 8-52). It lies upon the carpal extremities of the metacarpal bones and on the interosseous muscles, being covered by the oblique head of the adductor pollicis muscle, the flexor tendons of the fingers, and the lumbrical muscles. In nearly two-thirds of cases, the deep palmar arch lies deep to the ulnar nerve; in one-third of cases, it lies superficial to the nerve (to the palmar side). Occasionally it is doubled and encircles the ulnar nerve. Arising from the deep palmar arch are the **palmar metacarpal arteries**, **perforating branches**, and **recurrent branches**.

**PALMAR METACARPAL ARTERIES.** There are three or four palmar metacarpal arteries that arise from the convexity of the deep palmar arch (Figs. 8-51; 8-52). They course distally upon the interosseous muscles in the second, third, and fourth intermetacarpal spaces and anastomose, at the clefts of the fingers, with the common digital branches of the superficial palmar arch.

**PERFORATING BRANCHES.** Three perforating branches pass dorsally from the deep palmar arch, through the second, third, and fourth interosseous spaces, and between the heads of the corresponding dorsal interosseous muscles to anastomose with the dorsal metacarpal arteries.

**RECURRENT BRANCHES.** The recurrent branches arise from the concavity of the deep palmar arch. They ascend on the palmar aspect of the wrist, supply the intercarpal articulations, and end in the palmar carpal network.

## Arteries of the Thorax and Abdomen

From the aortic arch, the descending aorta courses along the posterior wall of the trunk through both the thoracic and abdominal cavities. Descending in the posterior mediastinum, the vessel is called the **thoracic aorta**; as it penetrates the diaphragm, it becomes the posterior abdominal aorta.

**THORACIC AORTA**

The **thoracic aorta**, contained in the posterior mediastinum, descends along the posterior wall of the thorax (Fig. 8-53). It begins at the lower border of the fourth thoracic vertebra, where it is continuous with the aortic arch, and ends anterior to the lower border of the twelfth thoracic vertebra, at the aortic hiatus in the diaphragm. At its origin, the thoracic aorta is situated on the left of the vertebral column, but as it descends, it approaches the median line. At its termination, the vessel lies directly anterior to the column. In its descent, the thoracic aorta describes a curve that is concave ventrally, and because its thoracic branches are small, there is no significant decrease in its diameter (Fig. 8-53).

**RELATIONS.** The **thoracic aorta** is related *anteriorly* to the root of the left lung, the pericardium, the esophagus, and the diaphragm, and *posteriorly* to the vertebral column and the hemiazygos veins. *On the right side* of the thoracic aorta are the azygos vein and thoracic duct, and *on the left side*, the left pleura and lung. The esophagus, with its accompanying plexus of nerves, lies to the right side of the upper thoracic aorta. More inferiorly in the thorax it is placed anterior to the aorta, but as it nears the diaphragm, it is situated to the left side of the aorta.

### Branches of the Thoracic Aorta

The thoracic aorta gives off visceral branches to organ structures in the thorax as well as parietal branches to the walls of the thoracic cavity. They are:

- Visceral Branches
  - Pericardial
  - Bronchial
  - Esophageal
  - Mediastinal
- Parietal Branches
  - Posterior intercostal
  - Subcostal
  - Superior phrenic

**PERICARDIAL BRANCHES**

The pericardial branches of the thoracic aorta consist of two or three small vessels that are distributed to the posterior surface

**FIG. 8-53.** The aortic arch and the descending thoracic aorta viewed from the left side with the left lung removed. The pericardium has been opened to expose the left side of the heart.

of the pericardium. They also supply some of the posterior mediastinal lymph nodes and anastomose with the pericardiophrenic branches of the internal thoracic artery.

### BRONCHIAL ARTERIES

The bronchial arteries vary in number, size, and origin. There is as a rule only one **right bronchial artery**, which arises from the third posterior intercostal artery (the first intercostal artery that comes from the aorta) or from the upper left bronchial artery. There are usually two **left bronchial arteries** and these arise from the thoracic aorta. The upper left bronchial arises oppo-

site the fifth thoracic vertebra, while the lower left bronchial artery stems from the aorta just below the level of the left bronchus. Each vessel courses along the posterior surface of its bronchus, dividing and subdividing along the bronchial tubes, supplying them, the areolar tissue of the lungs, and the bronchial lymph nodes. They also send a few twigs to the esophagus, to bronchial lymph nodes, and to the pericardium.

### ESOPHAGEAL ARTERIES

There are four or five esophageal arteries, which arise from the ventral aspect of the aorta and pass obliquely downward to the

esophagus, on which they form a chain of anastomoses. Additionally, these vessels anastomose with the esophageal branches of the inferior thyroid arteries and with ascending branches from the left inferior phrenic and left gastric arteries.

### MEDIASTINAL BRANCHES

Numerous small mediastinal branches arise from the thoracic aorta to supply lymph nodes, vessels, nerves, and loose areolar tissue in the posterior mediastinum, as well as some of the adjacent mediastinal pleura.

### POSTERIOR INTERCOSTAL ARTERIES

There usually are nine pairs of posterior intercostal arteries which branch from the thoracic aorta. They arise from the dorsal aspect of the aorta and are distributed to the lower nine intercostal spaces. The first two intercostal spaces are supplied by the supreme intercostal artery, which is a branch of the costocervical trunk from the subclavian artery. The **right posterior intercostal arteries** are longer than the left because the aorta is positioned to the left side of the vertebral column. They pass across the bodies of the vertebrae dorsal to the esophagus, thoracic duct, and azygos vein and are covered by the right lung and pleura. The **left posterior intercostal arteries** initially course dorsally, curving along the sides of the vertebral bodies and being covered by the left lung and pleura. The two uppermost vessels are crossed by the left superior intercostal vein, the lower vessels by the accessory hemiazygos and hemiazygos veins (Fig. 8-53). The further course of the posterior intercostal arteries is practically the same on both sides. Opposite the heads of the ribs, the sympathetic trunk passes anterior to them, and the splanchnic nerves descend anterior to the lower posterior intercostal arteries.

Each posterior intercostal artery crosses its corresponding intercostal space obliquely toward the angle of the next rib above and is continued ventrally in the costal groove. (This portion of the artery at one time was called the ventral ramus.) It is placed at first between the pleura and the internal posterior intercostal membrane. It then courses anteriorly around the intercostal space, lying between the internal inter-

costal muscle and the innermost intercostal muscle. Anteriorly, it anastomoses with the anterior intercostal branch of the internal thoracic or of the musculophrenic artery. Each artery is accompanied by a vein and a nerve, the former placed above and the latter below the artery (Fig. 8-53). This relationship exists except in the posterior part of the upper intercostal spaces, where the artery, which must ascend to the space, initially lies below the nerve and then between the nerve and vein. The third posterior intercostal artery (first aortic) anastomoses with the supreme intercostal artery, which branches from the costocervical trunk, and may form the chief supply of the second intercostal space. The lowest two posterior intercostal arteries are continued anteriorly from the intercostal spaces into the anterior abdominal wall and anastomose with the subcostal, superior epigastric, and lumbar arteries.

### Branches of the Posterior Intercostal Artery

In its course from the aorta around the thoracic wall, each posterior intercostal artery gives off several branches. These are the following:

- Dorsal
- Collateral intercostal
- Muscular
- Lateral cutaneous
- Mammary

**DORSAL BRANCH.** The dorsal branch of each posterior intercostal artery is a large vessel that courses backward through a space that is bounded above and below by the necks of the ribs, medially by the body of a vertebra, and laterally by a superior costotransverse ligament. It gives off a **spinal branch** which enters the vertebral canal through the intervertebral foramen and is distributed to the vertebrae, the spinal cord, and its membranes. The dorsal branch then courses over the transverse process of the vertebra, accompanied by the dorsal ramus of the segmentally corresponding thoracic spinal nerve. It supplies branches to the muscles of the back and cutaneous vessels which course with corresponding cutaneous branches of the dorsal ramus of the spinal nerve.

**COLLATERAL INTERCOSTAL BRANCH.** The collateral intercostal branch comes off from the

posterior intercostal artery near the angle of the rib and descends to the upper border of the rib below, along which it courses to anastomose with the intercostal branch of the internal thoracic artery.

**MUSCULAR BRANCHES.** Muscular branches arise from the posterior intercostal artery to supply the intercostal and pectoral muscles and the serratus anterior. They anastomose with the supreme thoracic and lateral thoracic branches of the axillary artery.

**LATERAL CUTANEOUS BRANCHES.** Lateral cutaneous branches arise from the posterior intercostal artery at about the midaxillary line. They penetrate laterally through the intercostal and serratus anterior muscles in company with the lateral cutaneous branches of the thoracic nerves. Achieving the superficial fascia, the vessels divide into anterior and posterior branches that course in a segmental manner to supply the skin and superficial fascia overlying an intercostal space. In the third, fourth, and fifth intercostal regions the anterior branches reach the lateral part of the mammary gland in the female and are sometimes called the *lateral* or *external mammary branches*.

**MAMMARY BRANCHES.** After giving off the lateral cutaneous branches, the posterior intercostal arteries continue around within the intercostal space, eventually to penetrate the skin and superficial fascia more anteriorly. In the third, fourth, and fifth spaces, (medial) mammary branches arise to reach the medial part of the base of the breast. They increase considerably in size during the period of lactation.

#### SUBCOSTAL ARTERIES

The subcostal arteries are so named because they lie below the last ribs. As such, they cannot be considered true intercostal arteries, but they are the lowest pair of arteries derived from the thoracic aorta, and they are in series with the other pairs of posterior intercostal arteries. Each artery passes along the lower border of the twelfth rib dorsal to the kidney and ventral to the quadratus lumborum muscle; it is accompanied by the ventral ramus of the twelfth thoracic or subcostal nerve. It then pierces the posterior aponeurosis of the transversus abdominis, and passing between this muscle and the internal oblique, it anastomoses with the superior epigastric, the lowest true intercos-

tal, and the lumbar arteries. Each subcostal artery gives off a dorsal branch, which has a distribution similar to those of posterior intercostal arteries.

#### SUPERIOR PHRENIC ARTERIES

The superior phrenic arteries are small vessels that arise from the lower part of the thoracic aorta. They are distributed to the dorsal part of the upper surface of the diaphragm and anastomose with the musculophrenic and pericardiophrenic arteries.

A small **aberrant artery** is sometimes found arising from the right side of the thoracic aorta near the origin of the right bronchial. It passes upward and to the right behind the trachea and the esophagus and may anastomose with the right supreme intercostal artery. It represents the remains of the **right dorsal aorta**, and in a small proportion of cases, it is enlarged to form the first part of the right subclavian artery.

#### ABDOMINAL AORTA

The abdominal aorta begins in the midline at the aortic hiatus of the diaphragm, ventral to the lower border of the body of the last thoracic vertebra. Descending anterior to the vertebral column, it ends on the body of the fourth lumbar vertebra, commonly a little to the left of the midline, by dividing into the two common iliac arteries. It diminishes rapidly in size as it descends in the abdomen because of the many large vessels that branch from it. As the aorta lies upon the bodies of the vertebrae, it displays a curve that is convex anteriorly. The summit of the convexity corresponds to the third lumbar vertebra. The aortic bifurcation may be roughly judged on the surface of the abdomen to occur slightly to the left of the midline at a site about 2.54 cm below the umbilicus. This is approximately at the level of a line drawn between the most superior extent of the iliac crests.

**RELATIONS.** The upper part of the **abdominal aorta** is covered *anteriorly* by the lesser omentum and stomach, dorsal to which are the branches of the celiac artery and the celiac plexus. Below these are the splenic vein, the pancreas, the left renal vein, the inferior part of the duodenum, the mesentery, and the aortic plexus. *Posteriorly*, the abdominal aorta is separated from the lumbar vertebrae and intervertebral discs by the anterior longitudinal liga-

ment and the second, third, and fourth left lumbar veins. On its *right side*, the abdominal aorta is related above to the azygos vein, cisterna chyli, thoracic duct, and the right crus of the diaphragm, the latter separating it from the proximal part of the inferior vena cava and the right celiac ganglion. More caudally in the abdomen, the right side of the aorta is in contact with the inferior vena cava. On the *left side*, the upper part of the abdominal aorta is related to the left crus of the diaphragm and the left celiac ganglion; somewhat lower are the fourth or ascending part of the duodenum, the duodenojejunal junction, and some coils of the small intestine.

**COLLATERAL CIRCULATION.** A degree of collateral circulation is provided by several anastomoses interconnecting vessels that arise above the aorta with others that arise below, or anastomoses between higher and lower branching vessels from the aorta itself. Thus, an anastomosis is found on the anterior wall of the trunk between the internal thoracic artery from the subclavian and the inferior epigastric ar-

tery, which branches from the external iliac. There is a free communication between the superior and inferior mesenterics, if an obstruction or ligature is placed between these vessels. When the point of ligature is below the origin of the inferior mesenteric (as is more common), collateral circulation is achieved between the inferior mesenteric artery and the internal pudendal artery of the pelvis. Other anastomoses exist between the lumbar arteries and the branches of the internal iliac. To these examples of collateral circulation can be added many others that protect regions of the body and organs that suffer diminished circulation.

### Branches of the Abdominal Aorta

The branches of the abdominal aorta may be divided into three sets: visceral, parietal, and terminal (Fig. 8-54).

FIG. 8-54. The abdominal aorta and its principal branches in the male.

Visceral Branches  
 Celiac trunk  
 Superior mesenteric  
 Inferior mesenteric  
 Middle suprarenal  
 Renal  
 Testicular  
 Ovarian  
 Parietal Branches  
 Inferior phrenic  
 Lumbar  
 Middle sacral  
 Terminal Branches  
 Common iliac

The **visceral branches** are distributed to the organs in the abdomen, and of these the celiac trunk and the superior and inferior mesenteric arteries are unpaired, whereas the middle suprarenals, renals, testicular, and ovarian are paired. The **parietal branches** supply the diaphragm from below as well as the posterior abdominal wall, and of these the inferior phrenics and lumbar are paired, while the middle sacral is unpaired. The **terminal branches** descend to supply the organs of the pelvis, the pelvic wall, and the lower extremities; of course, the common iliacs are paired (Fig. 8-54).

### CELIAC TRUNK

The celiac trunk is a short thick vessel that ranges from 7 to 20 mm in diameter and arises from the aorta just below the aortic hiatus of the diaphragm (Figs. 8-54; 8-55). It is covered by the peritoneum of the dorsal wall of the lesser sac (omental bursa). On its right side are the right celiac ganglion, the right crus of the diaphragm, and the caudate lobe of the liver. On its left side are the left celiac ganglion, the left crus of the diaphragm, and the cardiac end of the stomach. Below it is related to the upper border of the pancreas and the splenic vein. A short distance below its origin from the aorta (i.e., from 1 mm to 2.2 cm, but averaging about 1.25 cm), the aorta gives origin to the superior mesenteric artery.

#### Branches of the Celiac Trunk

After a short course of about 1 to 2 cm, the celiac trunk usually divides into three large branches (Figs. 8-55; 8-57). These are the:

Left gastric

Hepatic  
 Splenic

**VARIABILITY IN THE BRANCHING OF THE CELIAC TRUNK.** The most constant feature of this artery is the variability of its branching and of the routes by which blood reaches the organs that it principally supplies. According to Michels (1955), whose descriptions and statistics are followed in this account, the stomach, liver, pancreas, duodenum, and spleen are the organs supplied, and they can conveniently be used to designate the important variations.

A *gastrohepatosplenic trunk* has the classic branches: a left gastric, a common hepatic, and a splenic artery. This is the usual pattern (89%), and it gives origin to all its expected sub-branches in 64.5%, and in the remainder there are supernumerary or accessory branches.

An *hepatosplenic trunk* (3.5%) has hepatic and splenic arteries, but the left gastric arises independently from the aorta or from the hepatic or splenic arteries.

A *gastrosplenic trunk* (5.5%) has the left gastric and splenic arteries, but the hepatic arises from the aorta or from the superior mesenteric artery.

An *hepatogastric trunk* (1.5%) has the left gastric and hepatic arteries, but the splenic arises from the aorta or from the superior mesenteric artery.

In rare instances the celiac trunk and superior mesenteric arteries are combined.

#### Left Gastric Artery

The left gastric artery most commonly is the first branch of the celiac trunk, arising near its middle part (Figs. 8-55; 8-57). Being 4 to 5 mm in diameter, it is the smallest of the three branches off the celiac trunk, but it is much larger than the right gastric artery, which usually derives from the common hepatic artery. Frequently (25%), the left gastric arises from the termination of the celiac trunk together with the hepatic and splenic arteries. The vessel is covered by that part of the parietal peritoneum of the dorsal abdominal wall which forms the dorsal layer bounding the omental bursa. Initially, the left gastric artery courses anteriorly, upward, and to the left in a gentle curve. It raises a crescentic ridge of peritoneum called the gastrophrenic fold and reaches the anterior wall of the omental bursa near the cardiac end of the stomach, accompanied by the coronary vein. Here it reverses its direction and, lying between the two leaves of the lesser omentum, gives off a **cardioesophageal branch** before bifurcating into a **ventral** and a **dorsal branch**.

The **cardioesophageal branch** arises before the terminal bifurcation of the left gas-

**Fig. 8-55.** The celiac trunk and its branches. The liver has been elevated to reveal the porta hepatis and the gallbladder. Note that the lesser omentum and the anterior layers of the greater omentum have been cut. The arterial supply along the lesser curvature is represented by a double arcade.

tric artery. It is distributed to the cardia of the stomach and the lower esophagus by one to three smaller vessels.

The **ventral branch** of the left gastric is distributed to the anterior surface of the stomach by dividing into two or three smaller arteries.

The **dorsal branch** of the left gastric artery courses along the *lesser curvature* of the stomach, giving branches to the posterior surface of the stomach and usually anastomosing with the right gastric artery (Figs. 8-55; 8-57).

**VARIATIONS INVOLVING THE LEFT GASTRIC ARTERY.** The left gastric artery was found to be a branch of the aorta in 2.5% of cadavers studied, of a gastrosplenic trunk in 4.5%, and of an hepatogastric trunk in 1.5%. An **accessory left gastric artery** arose from the splenic in 6%, from the left hepatic in 3%, and from the celiac trunk in 2% of 200 bodies studied by Michels (1953).

An **aberrant left hepatic artery** branches from the left gastric artery just proximal to its bifurcation in 23% of cadavers studied. In considering ligation of the left gastric artery, it is important to realize that these aberrant left hepatic arteries completely replace the regular left hepatic artery in supplying the

left lobe of the liver in about half (11.5%) the aforementioned cases, and are accessory to the left lobe in the rest. It may be as large as 3 to 5 mm in diameter, and, lying between the two layers of the lesser omentum, it courses upward about 6 cm toward the esophagus. It then crosses the caudate lobe and enters the liver substance at the fissure for the ligamentum venosum. Because of this frequent origin of the left hepatic, the left gastric was named the gastrohepatic artery by Haller as early as 1756.<sup>1</sup>

The inferior phrenic arteries also may arise from the left gastric.

### Hepatic Artery

The hepatic artery, arising from the celiac trunk, is slightly smaller (7 to 8 mm) than the splenic artery in the adult, but is the largest branch of the celiac trunk in the fetus (Figs. 8-55 to 8-57). Its first part is horizontal, running from left to right along the upper border of the head of the pancreas to the pylorus or first part of the duodenum, where it usually gives off the **right gastric artery**. Behind the duodenum, the hepatic artery gives rise to the **gastroduodenal artery**, and then the main stem of the vessel turns superiorly to course toward the liver. It is covered by the peritoneum of the dorsal wall of the omental bursa, which is raised thereby into the right hepatopancreatic fold. It then passes between the layers of the hepatoduodenal ligament (lesser omentum) to the porta hepatis where it lies ventral to the epiploic foramen, having the common bile duct to its right and the portal vein dorsal to it. Frequently a distinction is made between two parts of the hepatic artery. That portion coursing from the celiac trunk to where the gastroduodenal artery branches is called the **common hepatic artery**, and the part coursing in the porta hepatis from which stem the lobar hepatic branches is called the **proper hepatic artery** (Figs. 8-55; 8-56). At a variable distance from the liver, the proper hepatic artery gives rise to three terminal branches, the **right, left, and middle hepatic arteries**.

**VARIATIONS.** Of 200 bodies, 41.5% had one or more aberrant hepatic arteries, 50.5% had none, several bodies had two, and a few three aberrants. The common hepatic arose from the aorta in three specimens of the 200, from the superior mesenteric in five, and from the left gastric in one (Michels, 1953).

<sup>1</sup>Albrecht von Haller (1708-1777): A Swiss physiologist and anatomist.

**Fig. 8-56.** The arterial supply to the gallbladder. Observe that the cystic artery usually branches from the right hepatic artery. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, 1975.)

**BRANCHES OF THE HEPATIC ARTERY.** The hepatic artery gives rise to the **right gastric**, the **gastroduodenal**, the **right hepatic**, the **left hepatic**, and the **middle hepatic arteries**.

**RIGHT GASTRIC ARTERY.** The right gastric artery is much smaller and less constant than the left gastric (Figs. 8-55; 8-57). It arises with about equal frequency from the common hepatic artery (40%) or the left hepatic (40.5%). It may arise, however, from the gastroduodenal (8%) or even the right (5.5%) or middle (5%) hepatic arteries. The vessel passes between the layers of the lesser omentum to the pylorus, which it supplies with branches. It runs to the left along the lesser curvature of the stomach, supplying an extensive area with anterior and posterior branches, and anastomoses with the dorsal branch of the left gastric artery.

**GASTRODUODENAL ARTERY.** The gastroduodenal artery arises from the common hepatic trunk, usually about halfway between its celiac origin and its division into the hepatic branches (Figs. 8-55; 8-57). It may arise from

FIG. 8-57. The celiac artery and its branches; the stomach has been raised and the peritoneum removed.

the left hepatic artery (11%), the right hepatic (7%), the middle hepatic (1%), or more rarely from the celiac or superior mesenteric artery. It is important to note that at times the gastroduodenal artery may arise from a hepatic artery that is the sole blood supply to one of the lobes of the liver. Its ligation, therefore, should always be considered in relation to its origin.

The gastroduodenal artery is a short but thick vessel, and it usually lies to the left of the common bile duct. It then crosses the duct either dorsally or ventrally and descends behind the first part of the duodenum and in front of the neck of the pancreas to the lower border of the junction between the pylorus and the first part of the duodenum. After giving off branches to the pyloric end of the stomach, the pancreas, and the **supraduodenal** and **retroduodenal** branches, the gastroduodenal artery ends by dividing into the **right gastroepiploic** and **superior pancreaticoduodenal** arteries.

The **supraduodenal** artery, when present, frequently arises from the retroduodenal or gastroduodenal (but may arise from the common or proper hepatic, the right or left hepatic, the superior pancreaticoduodenal, or the right gastric). It is distributed to the upper, anterior, and posterior surfaces of the first 3 cm of the superior (first) part of the duodenum.

The **retroduodenal** artery also arises from the gastroduodenal above the duodenum, but may arise from one of the hepatic arteries (10%). It descends behind the duodenum along the left side of the common bile duct, crosses anterior to the supraduodenal portion of the duct, and forms the U-shaped **dorsal pancreaticoduodenal arcade**. This arcade supplies branches to all four parts of the duodenum, to the head of the pancreas, and to the common bile duct. The retroduodenal artery anastomoses with a dorsal branch of the inferior pancreaticoduodenal from the superior mesenteric artery.

The **right gastroepiploic artery** is the larger of the two terminal branches of the gastroduodenal and is much larger than the left gastroepiploic artery (Figs. 8-55; 8-57). It passes from right to left along the greater curvature of the stomach at a somewhat variable distance from the border of the organ. It lies between the two layers of the gastrosplenic ligament or the ventral two layers of the greater omentum when these are not adherent to the colon. It gives off a large ascending **pyloric branch** near its origin, and at its termination usually anastomoses with the left gastroepiploic branch of the splenic artery. It supplies a number of ascending **gastric branches** to the stomach and descending branches to the greater omentum. These latter long anterior **epiploic branches** extend around the free border of the omentum and, in the dorsal layer of the omentum, may anastomose with other gastric or with pancreatic arteries.

The **superior pancreaticoduodenal artery** arises from the gastroduodenal artery as the latter passes dorsal to the first part of the duodenum (Figs. 8-57; 8-58). It forms a loop on the anterior surface of the pancreas and runs along the groove between the pancreas and the descending (second) portion of the duodenum. The vessel is embedded within the substance of the pancreas and, dorsal to the head of the pancreas, anastomoses with the inferior pancreaticoduodenal artery, a

branch of the superior mesenteric artery. The loop supplies branches to the ventral surface of the distal three parts (descending, transverse, and ascending) of the duodenum. The **ventral pancreaticoduodenal arcade**, formed by the anastomosis of the superior and inferior pancreaticoduodenal arteries, supplies numerous branches to the pancreas and duodenum (Fig. 8-58).

**RIGHT HEPATIC ARTERY.** Near the porta hepatis and beyond the origin of the gastroduodenal artery, the right hepatic artery most frequently branches from the proper hepatic artery (Figs. 8-55 to 8-57). Aberrant right hepatic arteries have been found, however, in about one-quarter of cadavers studied. In over three-fifths of the bodies showing an anomalous origin for the right hepatic, the vessel arises from the superior mesenteric artery. The remainder may arise directly from the aorta, the celiac trunk, the gastroduodenal, or even the left hepatic.

At its origin from the proper hepatic artery, the right hepatic artery usually lies anterior to the portal vein and crosses dorsal to the hepatic duct to enter the **cystic triangle** (of Calot<sup>1</sup>), which is bounded by the common hepatic duct on the left, the cystic duct on the right, and the hilum of the liver above. The right hepatic then gives off the **cystic artery** and finally divides into two

<sup>1</sup>Jean F. Calot (1861-1944): A French surgeon.

**Fig. 8-58.** The arterial supply to the pancreas. Note that the head of the pancreas receives the anterior and posterior superior pancreaticoduodenal arteries from the gastroduodenal, whereas the body and tail of the pancreas receive the dorsal, great, and caudal pancreatic branches from the splenic artery. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 1975.)

main branches before entering the right lobe of the liver.

The **cystic artery** usually arises from the right hepatic artery to the right of the hepatic duct and within the cystic triangle (for boundaries, see p. 737). Normally it courses a short distance along the cystic duct to reach the neck of the gallbladder (Figs. 8-55; 8-56). At this site the artery divides into a **superficial branch**, which supplies the free peritoneal surface, and a **deep branch**, which supplies the posterior surface of the gallbladder, embedded in the liver. The two branches anastomose and supply twigs to the adjacent liver substance.

There was only a single cystic artery in 75% of the bodies studied, whereas in 25% there was an **accessory cystic artery**. Although 82% of the cystic arteries arose within the cystic triangle, 18% arose to the left of the hepatic duct and not in the triangle. These latter vessels had to cross (either in front of or behind) the hepatic duct to reach the gallbladder. In most instances in which there were two cystic arteries, they served as superficial and deep vessels, and both generally arose within the cystic triangle. However, the superficial vessel was more variable than the deep and, at times, was observed originating from the right hepatic to the left of the duct or from another artery. In only 5% of cases studied did the cystic artery arise from some vessel other than the right hepatic artery. In these, it arose from the proper hepatic artery or, very rarely, from the gastroduodenal artery.

**LEFT HEPATIC ARTERY.** The left hepatic artery usually divides into two branches, an upper and a lower, supplying twigs to the capsule of the liver and the caudate lobe before entering the substance of the left lobe (Figs. 8-55; 8-56).

Aberrant left hepatic arteries are found in about 25% of bodies studied. In these instances, the aberrant vessel was the only artery to the left lobe of the liver in about 60%, whereas in the remaining 40% the aberrant vessel was an accessory left hepatic artery. Most of the aberrant left hepatic arteries arose from the left gastric artery.

**MIDDLE HEPATIC ARTERY.** The middle hepatic artery enters the fossa for the round ligament and accompanies the middle hepatic duct to the quadrate lobe. It is the principal supply for this lobe and sends twigs to the round ligament and sometimes to the left

lobe. The middle hepatic artery arises from the right hepatic in 45% of cases, from the left hepatic in 45%, and from other sources in 10%.

### Splenic (or Lienal) Artery

The splenic or lienal artery is the largest branch of the celiac, and it passes horizontally to the left along the pancreas to reach the spleen. It varies from 8 to 32 cm in length and is usually tortuous (Figs. 8-55; 8-57; 8-58). The **first part**, before it reaches the pancreas, forms a short arc, which swings down and to the right, then across the aorta to the upper border of the pancreas. The **second part** lies along a groove in the upper part of the dorsal surface of the body of the pancreas. It is the most tortuous and undulating part and has one or more loops or coils, but seldom courses far from the pancreas. The **third part** leaves the upper border of the pancreas to cross obliquely the anterior surface of the pancreas. At this point the vessel divides into its superior and inferior arteries in most subjects. The **fourth part** courses between the tail of the pancreas and the hilum of the spleen, and usually the superior and inferior vessels divide into five or more terminal branches at the splenic hilum.

The splenic artery, lying dorsal to the stomach, is covered by the peritoneum of the dorsal wall of the omental bursa. Its fourth part crosses anterior to the upper third of the left kidney and enters the splenic hilum by passing with the splenic vein in the substance of the lienorenal ligament.

**BRANCHES OF THE SPLENIC ARTERY.** The splenic artery generally supplies blood to three organs—the pancreas, the stomach, and the spleen. Its branches are the **pancreatic**, **left gastroepiploic**, **short gastric**, and **splenic**.

**PANCREATIC BRANCHES.** In addition to numerous twiglike branches to the neck, body, and tail of the pancreas, the splenic artery gives rise to three larger pancreatic vessels: the **dorsal pancreatic**, the **great pancreatic** (arteria pancreatica magna), and the **caudal pancreatic** (arteria caudae pancreatis) arteries (Fig. 8-58).

The **dorsal pancreatic artery** frequently arises from the first part of the splenic (39%), but it commonly has other origins, such as from the celiac (22%), one of the hepatic arteries (19%), the superior mesenteric (14%),

or the gastroduodenal (2%). It gives a number of twigs to the neck and body of the pancreas. It has two small **right branches**, one curving ventrally to supply the head of the pancreas and anastomosing with branches of the gastroduodenal; the other supplies the uncinate process with a plexus of vessels that anastomoses with the inferior pancreaticoduodenal artery. A branch often courses inferiorly to anastomose with superior mesenteric branches below the pancreas. The principal **left branch** is of considerable size and becomes the **transverse pancreatic artery**. This latter vessel takes a course to the left along the dorsocaudal surface of the pancreas for about two-thirds of its length and enters the substance of the gland to anastomose with other pancreatic branches from the splenic artery. It runs parallel to the main pancreatic duct for some distance, supplying it with branches. Its other long and short branches descend in the dorsal layer of the greater omentum as the **posterior epiploic arteries**, which anastomose with the anterior epiploics from the gastroepiploic arcade.

The **great pancreatic artery** (*arteria pancreatica magna*) arises from the second part of the splenic artery (Fig. 8-58). It is the largest pancreatic branch (2 to 4 mm diameter) and enters the left part of the body of the gland obliquely. It branches into right and left vessels. These vessels help the transverse splenic artery to supply the main pancreatic duct, and they anastomose with other pancreatic arteries.

The **caudal pancreatic artery** (*arteria caudae pancreatis*) arises from the third part of the splenic artery or one of its terminal branches (Fig. 8-58). It supplies vessels to the tail of the pancreas, anastomoses with the great and dorsal pancreatic branches, and supplies vessels to an accessory spleen when one is present.

**LEFT GASTROEPIPLOIC ARTERY.** The left gastroepiploic artery is the largest branch from the splenic artery and arises from its third part or from its inferior terminal artery (Figs. 8-55; 8-57). It reaches the stomach through the pancreaticolienal and gastrolial ligaments and courses along the greater curvature of the stomach from left to right within the anterior part of the greater omentum. Its branches are distributed to both surfaces of the stomach and to the greater omentum and anastomose with both

gastric and epiploic branches of the right gastroepiploic artery.

**SHORT GASTRIC ARTERIES.** The short gastric arteries consist of five to seven small branches, which arise near the end of the splenic artery and from its terminal divisions (Fig. 8-57). They pass from left to right, between the layers of the gastrolial ligament, and are distributed along the greater curvature of the fundus and cardiac end of the stomach. They anastomose with branches of the left gastric, left gastroepiploic, and inferior phrenic arteries.

**SPLenic BRANCHES.** The splenic artery divides about 3.5 cm from the spleen into a **superior** and an **inferior terminal branch**. These terminal branches may divide into several branches before entering the spleen, and there may even be intermediate branching. Division of the inferior terminal artery may be more complex than that of the superior, and it may give origin to the left gastroepiploic and inferior polar arteries. Arteries to the poles of the spleen are of frequent occurrence. The **superior polar artery** usually has its origin from the main splenic artery, or it may come directly from the celiac axis. **Inferior polar arteries** are more frequent than superior and arise most frequently from the left gastroepiploic, but may come from the splenic or inferior terminal branches. Cross anastomoses between the larger branches at the hilum are common.

#### SUPERIOR MESENTERIC ARTERY

The superior mesenteric artery is a large vessel that supplies the whole length of the small intestine except the superior part of the duodenum (Figs. 8-54; 8-57; 8-59; 8-62). It also supplies the cecum and the ascending part of the colon and about one-half of the transverse part of the colon (Fig. 8-59). It arises from the anterior surface of the aorta, about 1.25 cm below the celiac artery, at the level of the first lumbar vertebra, and is crossed at its origin by the splenic vein and the neck of the pancreas. The superior mesenteric artery then passes downward and forward, anterior to the uncinate process of the head of the pancreas and horizontal part of the duodenum, descending between the layers of the mesentery to the right iliac fossa. Here it is considerably diminished in size and anastomoses with one of its own branches, the ileocolic artery. In its descent

FIG. 8-59. The superior mesenteric artery and its branches.

it crosses ventral to the inferior vena cava, the right ureter, and the psoas major muscle, and forms an arch, the convexity of which is directed forward and downward to the left side. It is accompanied by the superior mesenteric vein, which lies to its right side (Fig. 8-59), and it is surrounded by the superior mesenteric plexus of nerves. Occasionally, the superior mesenteric artery arises from the aorta by a common trunk with the celiac trunk.

#### Branches of the Superior Mesenteric Artery

The branches of the superior mesenteric artery supply the head of the pancreas, the duodenum, the jejunum and ileum, the cecum and appendix, the ascending and transverse colon, and about half of the descending colon. They are the:

Inferior pancreaticoduodenal  
Jejunal and Ileal  
Ileocolic  
Right colic  
Middle colic

#### Inferior Pancreaticoduodenal Artery

The inferior pancreaticoduodenal artery arises from the superior mesenteric or from its first jejunal branch, opposite the upper border of the horizontal part of the duodenum (Figs. 8-57; 8-58). It courses to the right and frequently divides into anterior and posterior superior pancreaticoduodenal branches. The **anterior branch** ascends in front of the head of the pancreas to anastomose with the anterior branch of the superior pancreaticoduodenal. The **posterior branch** ascends on the dorsal surface of the head of the pancreas to anastomose with the

posterior branch of the superior pancreaticoduodenal. From these vessels branches are distributed to the head of the pancreas and to the descending and horizontal parts of the duodenum.

### Jejunal and Ileal Arteries

The jejunal and ileal arteries total about 12 to 15 in number (Figs. 8-59; 8-62). These intestinal vessels arise from the convex side of the superior mesenteric artery and are distributed to the jejunum and all of the ileum except its terminal portion. They run nearly parallel to one another between the layers of the mesentery, each vessel dividing into two branches. These unite with adjacent branches, forming a series of arches, the convexities of which are directed toward the intestine (Fig. 8-60). Branches from this first set of arches unite with similar branches from above and below, thus forming a second series of arches. In the ileal region the intestinal arteries may form a third, a fourth, or even a fifth series of arches, which dimin-

ish in size as they approach the intestine. In the short, upper jejunal part of the mesentery only one set of arches exists (Fig. 8-60), but more distally in the ileum, as the depth of the mesentery increases, multiple layers of arches or arcades are developed. From the terminal arches arise numerous small straight vessels, called *vasa recti*, which encircle the intestine and ramify between its coats. From the intestinal arteries small branches are given off to the lymph nodes and other structures between the layers of the mesentery.

### Ileocolic Artery

The ileocolic artery is the most inferior of the vessels that arise from the right side of the superior mesenteric artery (Figs. 8-59; 8-61). It passes downward and to the right toward the right iliac fossa, where it divides into a superior and an inferior branch. The **superior branch** of the ileocolic artery passes to the right behind the peritoneum and ascends to about the middle of the ascending colon, where it anastomoses with

**Fig. 8-60.** A small loop of jejunum showing the distribution of a jejunal artery coursing in the mesentery. Note that only one or two layers of arterial arches are formed by branches of the jejunal artery before the long *vasa recti* branch toward the intestine. (From an injected preparation of Hamilton Drummond.)

the descending branch of the right colic artery (Figs. 8-59; 8-61). The **inferior branch** of the ileocolic artery courses toward the superior border of the ileocolic junction and divides into colic, cecal, appendicular, and ileal branches (Fig. 8-61).

The **colic branch** passes upward along the ascending colon to supply several centimeters of its most proximal part. The **anterior** and **posterior cecal** are distributed to the front and back of the cecum. The **appendicular artery** (Fig. 8-61) descends dorsal to the termination of the ileum and enters the mes-

entery of the vermiform appendix, called the mesoappendix. Although the orientation of the appendix in the lower right quadrant is quite variable, the vessel courses along the free margin of the mesoappendix, ending in several branches that supply the organ. One of these is a recurrent branch, which supplies the posterior surface of the junction of the appendix with the cecum. The **ileal branch** courses to the left and upward along the distal part of the ileum, supplying it and anastomosing with the termination of the superior mesenteric.

**FIG. 8-61.** The branches of the iliocolic artery supplying the cecum and the appendix. Lower left insert shows that the appendix may extend in virtually any direction from the cecum. In nearly 65% of cases studied, it projects superiorly behind the cecum and in about 31% inferomedially, as drawn in the larger figure above.

FIG. 8-62. The arterial supply to the large colon.

### Right Colic Artery

The right colic artery arises directly from the right side of the superior mesenteric artery, or from a stem common to it and the ileocolic (Figs. 8-59; 8-62). It passes to the right, behind the peritoneum and anterior to the right testicular or ovarian vessels, the right ureter, and the psoas major muscle, toward the middle of the ascending colon. Sometimes the vessel lies at a higher level, and crosses the descending part of the duodenum and the caudal end of the right kidney. At the ascending colon, the right colic artery divides into a descending branch, which anastomoses with the ileocolic, and

an ascending branch, which anastomoses with the middle colic. These branches form arches, from the convexity of which vessels are distributed to the ascending colon, as far as the right colic flexure.

### Middle Colic Artery

The middle colic artery arises from the superior mesenteric just below the pancreas (Figs. 8-59; 8-62) and, passing anteriorly between the layers of the transverse mesocolon, divides into right and left branches. The **right branch** anastomoses with the right colic, and the **left branch** with the left colic, which arises from the inferior mesenteric.

The arches thus formed are placed about 4 cm from the transverse colon, to which they distribute branches.

### INFERIOR MESENTERIC ARTERY

The inferior mesenteric artery supplies nearly the left half of the transverse colon, the whole of the descending colon, the sigmoid colon, and the greater part of the rectum (Figs. 8-54; 8-62; 8-63). It is smaller than the superior mesenteric artery and arises from the aorta, about 3 or 4 cm above its bifurcation into the common iliac arteries. The origin of the inferior mesenteric artery is close to the lower border of the horizontal part of the duodenum, at the level of the middle of the third lumbar vertebra. The vessel descends behind the peritoneum, lying initially in front of, and then on the left side of, the aorta. It crosses the left common iliac artery, medial to the left ureter, and is continued into the lesser pelvis as the **superior rectal artery**, descending between the two layers of the sigmoid mesocolon and ending on the upper part of the rectum.

#### Branches of the Inferior Mesenteric Artery

The branches of the inferior mesenteric artery are initially directed to the left or inferiorly. They are the:

- Left colic
- Sigmoid
- Superior rectal

#### Left Colic Artery

The left colic artery courses to the left, deep to the peritoneum and anterior to the psoas major muscle (Fig. 8-62), and after a short but variable course, it divides into an ascending and a descending branch. The main stem of the artery or its branches cross the left ureter and left testicular or ovarian vessels. The **ascending branch** crosses in front of the left kidney and ends, between the two layers of the transverse mesocolon, by anastomosing with the middle colic artery. The **descending branch** courses down toward the sigmoid flexure and anastomoses with the highest sigmoid artery. From

the arches formed by these anastomoses, branches are distributed to the descending colon and the left part of the transverse colon.

### Sigmoid Arteries

Two or three sigmoid arteries branch from the continuing stem of the superior mesenteric artery and run obliquely downward and to the left behind the peritoneum and ventral to the psoas major muscle, the ureter, and the testicular or ovarian vessels (Figs. 8-62; 8-63). Their branches supply the caudal part of the descending colon and the sigmoid colon, anastomosing above with the left colic artery and below with the superior rectal artery.

### Superior Rectal Artery

The superior rectal artery (sometimes still called the superior hemorrhoidal artery) is the continuation of the inferior mesenteric artery. It descends into the pelvis between the layers of the sigmoid mesentery and crosses the left common iliac vessels (Figs. 8-62; 8-63). Opposite the third sacral vertebra, it divides into two branches, which descend one on each side of the rectum and, about 10 or 12 cm above the anus, separate into several small branches. These pierce the muscular coat of the bowel and course downward as straight vessels that are placed at regular intervals in the wall of the gut, between its muscular and mucous coats, to the level of the internal anal sphincter. From this site they form a series of loops around the lower end of the rectum and anastomose with the middle rectal branches of the internal iliac and with the inferior rectal branches of the internal pudendal (Figs. 8-62; 8-63).

**CLINICAL SIGNIFICANCE.** A rich anastomosis of arterial branches that supply the large intestine is formed from the ileocolic, right colic, middle colic, left colic, and sigmoid arteries. These vessels join in the formation of a series of interconnecting arcades, the pattern of which gives rise to a continuous vessel, called the **marginal artery of Drummond**, which courses along the inner perimeter of the large colon, extending from the ileocolic junction to the rectum. From the marginal artery branch straight vessels (*arteriae rectae*), which are directed to the

**Fig. 8-63.** The inferior mesenteric artery and the blood supply to the sigmoid colon, rectum, and anal canal. Note that the rectum receives its blood supply from three different sources. These are the superior rectal artery (1) from the inferior mesenteric artery; the middle rectal artery (2) from the internal iliac artery; and the inferior rectal artery (3) from the internal pudendal artery.

organ. The clinical benefit of this vascular pattern is appreciated by the surgeon, who frequently is required to ligate one or more branches of the mesenteric vessels in the resection of bowel and yet maintain the vascular integrity of the remainder of the large colon.

A **critical point** of anastomosis for the maintenance of the vascular supply to the distal sigmoid colon, however, is found between the fields supplied by the sigmoid vessels and the superior rectal artery. The pattern of blood supply to this region must be studied carefully because high ligation of the superior rectal artery may, in fact, result in the loss of vascularization to a portion of the distal sigmoid colon.

#### MIDDLE SUPRARENAL ARTERIES

Although there are three pairs of suprarenal arteries—superior, middle, and inferior, only the middle set of vessels arises directly from the aorta. The superior arises from the inferior phrenic, and the inferior suprarenal arises from the renal arteries. The middle suprarenal arteries are two small vessels that arise, one from each side of the aorta, opposite the superior mesenteric artery. They pass laterally and slightly upward, over the crura of the diaphragm, to the suprarenal glands, where they anastomose with supra-

renal branches from the inferior phrenic and renal arteries. In the fetus, these arteries are large.

### RENAL ARTERIES

The renal arteries are two large trunks that arise, one on each side of the aorta, immediately below the superior mesenteric artery at the level of the disc between the first and second lumbar vertebrae (Fig. 8-54). Each is directed across the crus of the diaphragm of the corresponding side, thus forming nearly a right angle with the aorta. The **right renal artery** is longer than the left because of the position of the aorta. It passes behind the inferior vena cava, the right renal vein, the head of the pancreas, and the descending part of the duodenum. The **left renal artery** arises somewhat more superiorly than the right. It courses dorsal to the left renal vein, the body of the pancreas, and the splenic vein, and is itself crossed by the inferior mesenteric vein. Before reaching the hilum of the kidney, each artery divides into four or five branches, most of which lie between the renal vein and the ureter. At the renal hilum, the renal vein is most anterior and the pelvis of the kidney is most posterior. The renal artery lies between the two; however, a few of its branches usually enter the kidney behind the renal pelvic origin of the ureter.

Each renal artery gives off some small **inferior suprarenal branches** to the suprarenal gland, the ureter, and the surrounding cellular tissue and muscles.

One or two **accessory renal arteries** are frequently found (23%), especially on the left side. These usually arise from the aorta and come off somewhat more frequently above the main renal artery than below. Instead of entering the kidney at the hilum, they usually pierce the upper or lower part of the organ.

### TESTICULAR ARTERIES

The testicular arteries are two long slender vessels that arise from the anterior aspect of the aorta a little below the renal arteries (see Fig. 8-54). Each passes obliquely downward and laterally behind the peritoneum, resting on the psoas major muscle. The **right testicular artery** lies anterior to the inferior vena cava and behind the horizontal portion of the duodenum, the middle colic and ileocolic arteries, and the terminal part

of the ileum. The **left testicular artery** courses behind the left colic and sigmoid arteries and the sigmoid colon. Each testicular artery crosses obliquely over the ureter and distal part of the external iliac artery to reach the deep inguinal ring (Fig. 8-70). Passing through the ring, the vessel accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum. Along its course, the testicular artery becomes tortuous and divides into several branches. Two or three of these accompany the ductus deferens and supply the epididymis, anastomosing with the artery of the ductus deferens. Others pierce the back part of the tunica albuginea and supply the substance of the testis. The testicular artery supplies one or two small branches to the ureter and, in the inguinal canal, gives one or two twigs to the cremaster muscle.

### OVARIAN ARTERIES

In the female the ovarian arteries are the homologues of the testicular arteries in the male. They are shorter than the testicular, and because they supply the ovaries, they do not pass out of the abdominal cavity. The origin and course of the first part of each artery are the same as those described for the testicular. Arriving at the superior inlet to the lesser pelvis, the ovarian artery passes medially between the two layers of the suspensory ligament of the ovary and of the broad ligament of the uterus, to be distributed to the ovary. Small branches supply the ureter and the uterine tube, and one passes on to the side of the uterus and anastomoses with the uterine artery. Other branches are distributed to the round ligament of the uterus, through the inguinal canal, and reach the skin of the inguinal region and the labium majus.

In the early stages of development, the testes or ovaries lie by the side of the vertebral column, below the kidneys, and the testicular or ovarian arteries are short. When the gonads descend into the scrotum or lesser pelvis, their arteries gradually lengthen.

### INFERIOR PHRENIC ARTERIES

The inferior phrenic arteries are two small vessels that supply the diaphragm, but their origin is subject to some variation (see Fig.

8-54). They may arise separately from the anterior aspect of the aorta, immediately above the celiac artery. In an almost equal number of instances, however, these vessels have been found arising from the celiac trunk. In nearly one-third of cadavers studied, the two inferior phrenic arteries arise by means of a common vessel instead of separately, and this may come from either the aorta or the celiac trunk. Less frequently these vessels may stem from the renal or accessory renal arteries, the left gastric artery, the hepatic arteries, and even the testicular arteries.

From their origin, the inferior phrenic arteries diverge from each other, cross the crura of the diaphragm, and course laterally in an oblique direction upon the abdominal surface of the diaphragm. The **left phrenic artery** passes behind the esophagus and then courses anteriorly on the left side of the esophageal hiatus. The **right phrenic artery** passes behind the inferior vena cava and then along the right side of the diaphragmatic foramen, which transmits that vein. Near the dorsal part of the central tendon of the diaphragm, each vessel divides into a medial and a lateral branch. The **medial branch** curves ventrally and anastomoses with the same vessel of the opposite side, and with the musculophrenic and pericardiophrenic arteries. The **lateral branch** passes toward the side of the thorax and anastomoses with the lower posterior intercostal arteries and with the musculophrenic artery. The lateral branch of the right phrenic gives off a few vessels to supply the wall of the inferior vena cava, and the left inferior phrenic gives off some branches to the esophagus.

Each inferior phrenic artery gives origin to several **superior suprarenal branches** to the suprarenal gland of its own side. The spleen and the liver also receive a few twigs from the left and right vessels respectively.

### LUMBAR ARTERIES

The lumbar arteries are in series with the posterior intercostal arteries. There are usually four on each side, and they arise from the dorsum of the aorta, opposite the bodies of the upper four lumbar vertebrae. A small fifth pair arising from the middle sacral artery is occasionally present, but more frequently lumbar branches of the iliolumbar

arteries take their place. The lumbar arteries run laterally and posteriorly on the bodies of the lumbar vertebrae, behind the sympathetic trunk, to the intervals between adjacent transverse processes of the vertebrae and are then continued into the abdominal wall. The right lumbar arteries pass behind the inferior vena cava, and the upper two on each side course dorsal to the corresponding crus of the diaphragm. The arteries of both sides pass beneath the tendinous arches, extending across the bodies of the lumbar vertebrae, which give origin to slips of the psoas major muscle. The vessels are then continued behind this muscle and the lumbar plexus, and cross the quadratus lumborum, the upper three arteries running behind and the last usually in front of that muscle. At the lateral border of the quadratus lumborum, they pierce the posterior aponeurosis of the transversus abdominis and are carried anteriorly between this muscle and the internal oblique. They anastomose with the lower posterior intercostal, the subcostal, the ilio-lumbar, the deep iliac circumflex, and the inferior epigastric arteries and with each other.

**BRANCHES OF THE LUMBAR ARTERIES.** In the interval between the adjacent transverse processes, each lumbar artery gives off a **dorsal ramus**, which is continued backward between the transverse processes and is distributed to the muscles and skin of the back. The dorsal ramus also furnishes a **spinal branch**, which enters the vertebral canal and is distributed similarly to spinal branches of the dorsal rami of the posterior intercostal arteries. **Muscular branches** are supplied from each lumbar artery and from its posterior ramus to the neighboring muscles. The lumbar arteries also send **vertebral branches** to the bodies of the lumbar vertebrae and small **renal branches** to the capsules of the kidney.

### MIDDLE SACRAL ARTERY

The middle sacral artery is a small vessel that arises from the dorsal aspect of the aorta a short distance above the bifurcation (Figs. 8-54; 8-62; 8-63). At times it arises from one of the two fifth lumbar arteries. It descends in the midline anterior to the fourth and fifth lumbar vertebrae, the sacrum, and the coccyx. At the tip of the coccyx, the middle sacral artery reaches the coccygeal body, which

is a nodular structure consisting of many arteriovenous anastomoses intermeshed in a dense connective tissue. On the last lumbar vertebra it anastomoses with the lumbar branch of the iliolumbar artery; anterior to the sacrum, it anastomoses with the lateral sacral arteries and sends small vessels into the anterior sacral foramina. It is crossed by the left common iliac vein and is accompanied by a pair of *venae comitantes*. These unite to form a single vessel, which opens into the left common iliac vein.

## Arteries of the Pelvis, Perineum, and Gluteal Region

The abdominal aorta terminates at its bifurcation into the two **common iliac arteries** (Figs. 8-54; 8-64; 8-65; 8-75). On each side these vessels divide and subdivide, eventually to supply the organs and walls of the pelvis, the perineum, and the gluteal region.

### COMMON ILIAC ARTERIES

Just to the left side of the body of the fourth lumbar vertebra, the abdominal aorta divides into the two common iliac arteries. These vessels diverge laterally as they descend from the end of the aorta, and each divides, opposite the intervertebral fibrocartilage between the last lumbar vertebra and the sacrum, into an **external** and an **internal iliac artery**. The former vessel supplies a good deal of the lower limb, while the latter vessel supplies the viscera and walls of the pelvis.

In addition to the terminal internal and external iliac branches, each common iliac artery gives off small branches to the peritoneum, the psoas major muscle, the ureter, and the surrounding areolar tissue, and occasionally gives origin to the iliolumbar or accessory renal arteries.

#### Right Common Iliac Artery

The right common iliac artery is usually somewhat longer than the left and passes more obliquely across the body of the last lumbar vertebra (Figs. 8-54; 8-65). It measures about 5 cm in length, and anterior to it

are the peritoneum, the loops of small intestine, branches of sympathetic nerves, and, at its point of division, the ureter. Posteriorly, it is separated from the bodies of the fourth and fifth lumbar vertebrae and the intervening disc by the terminations of the two common iliac veins and the commencement of the inferior vena cava. More deeply between the fifth vertebra and the psoas major muscle are the obturator nerve, the lumbosacral sympathetic trunk, and the iliolumbar branch of the internal iliac artery. Laterally, it is in relation above with the inferior vena cava and below with the right common iliac vein and the psoas major muscle. Medial to its upper part is the left common iliac vein.

#### Left Common Iliac Artery

The left common iliac artery, being a little shorter and thicker than the right, measures about 4 cm in length (see Fig. 8-54). It is related anteriorly to the peritoneum, loops of the small intestine, branches of sympathetic nerves, and the superior rectal artery. It is crossed at its point of bifurcation by the left ureter. Posteriorly are found the bodies of the fourth and fifth lumbar vertebrae and their intervening disc, and the disc between the fifth lumbar vertebra and the sacrum. Crossing behind the vessel between the fifth lumbar vertebra and the psoas major muscle are the lumbosacral sympathetic trunk, the obturator nerve, and the iliolumbar artery. Medial to the left common iliac artery are the left common iliac vein, the hypogastric plexus, and the middle sacral artery, while lateral to it is the psoas major muscle.

**VARIATIONS RELATED TO THE COMMON ILIAC ARTERIES.** The point of origin of the common iliac arteries varies according to the bifurcation of the aorta. In three-quarters of a large number of cases, the aorta bifurcated either anterior to the fourth lumbar vertebra or upon the disc between it and the fifth. The bifurcation is located, in one case out of nine, below, and in one out of eleven, above this point. In about 80% of cases studied, the aorta bifurcated within 1.25 cm above or below the level of the crest of the ilium, but more frequently below than above.

The point of division of the common iliac arteries into internal and external iliac branches varies greatly. In two-thirds of the cases studied, this division occurred between the last lumbar vertebra and the upper border of the sacrum, being above that point in one of eight cases and below it in one of six

FIG. 8-64. The iliac arteries and their branches.

cases. The left common iliac artery divides lower than the right more frequently.

The **relative lengths** of the two common iliac arteries also vary. The right common iliac was the longer in 37% of cases, the left in 31%; they were equal in 32%. The length of the arteries varied from 3.5 to 7.5 cm in 72% of the cases studied. Of the remaining 28%, 14% were shorter than 3.5 cm and 14% were longer than 7.5 cm. The shortest common iliac artery measured only 1.25 cm, the longest 11 cm. In rare instances, the right common iliac has been absent, and the external and internal iliac arteries arose directly from the aorta.

**COLLATERAL CIRCULATION.** The principal vessels contributing to collateral circulation after the application of a ligature to the common iliac are the anastomoses of (1) the middle rectal branch of the internal iliac with the superior rectal from the inferior mesenteric, (2) the uterine, ovarian, and vesical arteries of the opposite side with the same vessels on the ligated side, (3) the lateral sacral artery from the internal iliac and the middle sacral artery from the aorta, (4) the inferior epigastric artery from the external iliac with the internal thoracic artery, the lower posterior intercostal arteries, and the lumbar arteries, (5) the deep iliac circumflex from the external iliac artery and the lumbar arteries from the aorta, (6) the iliolumbar artery from the internal iliac with the last lumbar artery, and (7) the obturator artery, by means of its pubic branch, with the same vessel from the opposite side and with the inferior epigastric arteries, which anastomose with the superior epigastric arteries.

### Internal Iliac Artery

The internal iliac artery, also known as the **hypogastric artery**, begins at the bifurcation of the common iliac, anterior to the sacroil-

iac joint at the level of the lumbosacral disc (Figs. 8-64; 8-65; 8-75). It follows a short, curved course of about 4 cm, descending toward the greater sciatic foramen. Although it is an exceedingly variable artery in terms of the pattern of its branches, in slightly more than half the bodies it divides into an **anterior trunk** and a **posterior trunk**. It supplies the walls of the pelvis, the pelvic viscera, the buttock, the genital organs, and part of the medial thigh.

The internal iliac artery is covered anteriorly by peritoneum and in females is related to the ovary and uterine tube. It is also crossed by the ureter. Posterior to the vessel courses the internal iliac vein, the sacroiliac joint, and the lumbar contribution to the sacral plexus, called the lumbosacral trunk. Lateral to the internal iliac artery is the internal iliac vein, which separates the artery from the psoas major and the obturator nerve. Medial to the right artery are the terminal loops of the ileum, and medial to the left artery is the flexure of the sigmoid colon as it becomes the rectum.

**In the fetus**, the internal iliac artery is twice as large as the external iliac; it is the direct continuation of the common iliac. It ascends along the side of the bladder and runs superiorly on the inner aspect of the anterior wall of the abdomen to reach the umbilicus, converging toward the same vessel from the opposite side. Having passed through the umbilical opening, the two arteries, which are now called **umbilical arteries**, enter the umbilical cord and become

coiled around the umbilical vein, to ramify ultimately in the placenta.

**After birth**, when the placental circulation ceases, only the pelvic portion of the umbilical artery remains patent, becoming in the adult the internal iliac and first part of the superior vesical artery. The remainder of the vessel is converted into a solid fibrous cord, the **medial umbilical ligament**, which extends from the pelvis to the umbilicus.

**COLLATERAL CIRCULATION.** After ligation of the internal iliac artery, collateral circulation is accomplished by anastomoses (1) of the ovarian artery from the aorta and the uterine artery; (2) between the vesical arteries of the opposite side and the same vessels on the ligated side; (3) between the middle rectal branches of the internal iliac and the superior rectal artery from the inferior mesenteric; (4) between the obturator artery and the inferior epigastric and medial femoral circumflex arteries, and by

means of the pubic branch of the obturator artery and the same vessel from the opposite side; (5) between the circumflex and perforating branches of the deep femoral artery and the inferior gluteal; (6) between the superior gluteal artery and the posterior branches of the lateral sacral arteries; (7) between the iliolumbar artery and the last lumbar; (8) between the lateral sacral artery and the middle sacral; and (9) between the iliac circumflex and the iliolumbar and superior gluteal arteries.

### Branches of the Internal Iliac Artery

The branches of the internal iliac artery are subject to considerable variation in their origin. The division into **anterior** and **posterior trunks** is seldom complete, and any two branches may arise from a common trunk. However, the distribution to tissues and organs of the individual branches is more con-

**FIG. 8-65.** The right internal and external iliac arteries and their branches viewed from the left side. (From Benninghoff and Goertler, 1975.)

stant, and the different vessels may be grouped as follows: visceral, anterior parietal, and posterior parietal.

- Visceral
  - Umbilical
  - Inferior vesical
  - Middle rectal
  - Uterine
  - Vaginal
- Anterior Parietal
  - Obturator
  - Internal pudendal
- Posterior Parietal
  - Iliolumbar
  - Lateral sacral
  - Superior gluteal
  - Inferior gluteal

**VARIATIONS IN THE BRANCHING PATTERN OF THE INTERNAL ILIAC ARTERY.** In a series of 130 consecutive dissections, Ashley and Anson (1941) recorded the pattern of variation in the branching of the internal iliac artery. In the most common pattern (58%), the inferior gluteal and internal pudendal arteries were derived from a common stem, and the umbilical and superior gluteal arteries arose above them by separate stems. In 17%, the inferior and superior gluteal arteries arose from one stem and the umbilical and pudendal arteries arose from another stem. In 10%, the internal pudendal, inferior gluteal, and umbilical arteries arose by a common stem, and the superior gluteal branched separately. In 8%, the umbilical and internal pudendal arteries arose separately above a common stem for the two gluteal arteries. In these instances the internal pudendal artery appeared to be the continuation of the internal iliac, a condition described by some authors as a more primitive type found in lower animals. Five other patterns were described, but their appearance was less frequent than the above. The obturator was probably the most variable branch, and a few of its patterns are described with that artery.

#### UMBILICAL ARTERY

The umbilical arteries are generally the first of the visceral branches that arise from the internal iliac arteries (Fig. 8-64). During intrauterine life, these vessels form the principal channels from the fetal internal iliac arteries to the umbilical cord. By adulthood, most of the vessel on each side becomes a fibrous cord called the **medial umbilical ligament**; however, it does retain a patent lumen for a short distance beyond the internal iliac artery. Just proximal to the site where the umbilical artery becomes obliterated,

the umbilical artery on each side gives rise to several **superior vesical branches** which supply the bladder. It also may give rise to the **artery of the ductus deferens** and, at times, to the **middle vesical artery** as well.

**SUPERIOR VESICAL ARTERIES.** From one to four small superior vesical arteries arise from the umbilical artery to supply the upper part of the bladder (Figs. 8-64; 8-65). In nearly 75% of cases, there are two or three superior vesical arteries on each side.

**ARTERY OF THE DUCTUS DEFERENS.** This slender vessel may arise directly from the umbilical artery, or from one of the superior vesical arteries, or from the middle vesical artery (Fig. 8-64). It accompanies the ductus in its course to the testis, where it anastomoses with the testicular artery.

**MIDDLE VESICAL ARTERY.** This vessel may arise directly from the umbilical artery or as a branch of the superior vesicle. It is distributed to the fundus of the bladder and the seminal vesicles and anastomoses with the other vesical arteries. Frequently, one or more **ureteric branches** arise from the middle vesical artery or the artery to the ductus deferens to supply the lower end of the ureter. These anastomose with other vessels that supply the more superior parts of the ureter.

#### INFERIOR VESICAL ARTERY

The inferior vesical artery sometimes arises from the anterior trunk of the internal iliac artery in common with the middle rectal. It may, however, arise from a trunk in common with the internal pudendal and superior gluteal arteries, or as a branch from the internal pudendal (Fig. 8-65). It is usually a single branch and is distributed to the fundus of the bladder, the prostate, and the seminal vesicles. The branches to the prostate communicate with the corresponding vessels of the opposite side.

#### MIDDLE RECTAL ARTERY

The middle rectal artery may arise from the anterior trunk of the internal iliac with the inferior vesical artery, but more frequently it arises with or from the internal pudendal artery or from the inferior gluteal artery (Figs. 8-64; 8-65). Only rarely is it completely absent. It is distributed to the rectum, anastomosing with the inferior vesical and

with the superior and inferior rectal arteries. It gives branches to the seminal vesicles and the prostate.

### UTERINE ARTERY

The uterine artery generally arises from the medial surface of the anterior trunk of the internal iliac (Fig. 8-66). It continues medially on the levator ani toward the cervix of the uterus. At about 2 cm from the cervix it crosses above and in front of the ureter, to which it supplies a small branch. Reaching the side of the uterus, it ascends in a tortuous manner between the two layers of the broad ligament to the junction of the uterine tube and uterus. It then runs laterally toward the hilum of the ovary and ends by anastomosing with the ovarian artery. It supplies branches to the uterine cervix and others to the vagina. These latter vessels anastomose with branches of the vaginal arteries and form with them the median longitudinal vessels called the **azygos arteries of the vagina**. There are usually two azygos arteries, one of which courses down the ventral and the other down the dorsal surface of the vagina (Fig. 8-66). The uterine artery supplies numerous branches to the body of the

uterus, and from its terminal portion twigs are distributed to the uterine tube and the round ligament of the uterus before anastomosing with the ovarian artery (Fig. 8-66).

### VAGINAL ARTERIES

The vaginal arteries are represented by one, two, or even three vessels which may arise directly from the anterior trunk of the internal iliac artery (Fig. 8-66). More frequently one or more of the vaginal arteries arises from the uterine artery or even from the inferior vesical artery. Approaching the vagina at its junction with the uterine cervix, the vaginal arteries then descend upon the vagina, supplying its mucous membrane. They send branches to the bulb of the vestibule, the fundus of the bladder, and the contiguous part of the rectum, and assist in forming the azygos arteries of the vagina (Fig. 8-66).

### OBTURATOR ARTERY

The obturator artery arises most frequently from the ventral or medial surface of the internal iliac artery or from one of its branches (Figs. 8-64; 8-65; 8-70; 8-74). It

FIG. 8-66. The arteries of the female internal organs of reproduction as seen from behind.

courses ventrally on the lateral wall of the pelvis to the obturator canal, through which it courses as it leaves the pelvic cavity to reach the thigh, where it divides into anterior and posterior branches. Lateral to the obturator artery in the pelvis is the obturator fascia covering the obturator internus muscle. The vessel is crossed medially by the ureter and ductus deferens, and it is covered by the peritoneum. The obturator nerve accompanies the artery and courses above the vessel, while the obturator vein courses below.

#### Branches of the Obturator Artery

Within the pelvis, the obturator artery gives rise to **iliac, vesical, and pubic branches**. Outside the pelvis, the vessel divides at the margin of the obturator foramen into an **anterior** and a **posterior branch**, which encircle the foramen under cover of the obturator externus muscle.

**ILIAC BRANCHES.** The iliac branches of the obturator artery ascend in the iliac fossa and supply the iliacus muscle and send nutrient vessels to the ilium; they also anastomose with branches of the iliolumbar artery.

**VESICAL BRANCH.** The vesical branch of the obturator courses medially and backward to help supply the bladder.

**PUBIC BRANCH.** The pubic branch arises from the obturator artery just before it leaves the pelvic cavity. This branch ascends upon the inside of the pubis and communicates with the same vessel from the opposite side and with the inferior epigastric artery.

**ANTERIOR BRANCH.** The anterior branch of the obturator artery courses ventrally on the outer surface of the obturator membrane and then curves downward along the anterior margin of the foramen. It distributes branches to the obturator externus, pectineus, the adductor muscles, and the gracilis, anastomosing with the posterior branch and with the medial femoral circumflex artery.

**POSTERIOR BRANCH.** The posterior branch of the obturator artery follows the posterior margin of the foramen and divides into two branches. One branch runs anteriorly on the inferior ramus of the ischium, where it anastomoses with the anterior branch of the obturator. The other branch gives twigs to the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal. It

also supplies the **acetabular** or articular branch, which enters the hip joint through the acetabular notch, ramifies in the fat at the bottom of the acetabulum, and sends a twig deep to the transverse acetabular ligament accompanying the ligament of the head of the femur.

**VARIATIONS OF THE OBTURATOR ARTERY.** The obturator artery was found to arise from the internal iliac or one of its branches in nearly 70% of 320 bodies studied (Pick, Anson, and Ashley, 1942). It arose from the main vessel in 23%, from the anterior trunk in 20%, from the posterior trunk in 3%, from the superior gluteal in 11%, from the inferior gluteal in 9%, and from the internal pudendal or external iliac in 2 or 3%. The origin of the obturator artery from the inferior epigastric artery occurred in 27% of cases. In these instances, the artery lies in contact with the external iliac vein. Its course toward the obturator canal is relevant clinically during operations for the repair of a femoral hernia. If its course is lateral to the lacunar ligament, repair is relatively safe. If, however, the obturator artery *curves along the free margin of the lacunar ligament*, it can encircle the neck of a hernial sac and be injured during the hernial repair (Fig. 8-67).

#### INTERNAL PUDENDAL ARTERY

The internal pudendal artery (Figs. 8-64; 8-65; 8-68) supplies the perineum and external organs of generation, and although the course of the artery is the same in the two sexes, the vessel is smaller in the female than in the male, and the distribution of its branches somewhat different.

#### Internal Pudendal Artery in the Male

The internal pudendal artery in the male courses downward and laterally toward the lower border of the greater sciatic foramen and emerges from the pelvis between the

**FIG. 8-67.** An obturator artery is shown arising from the inferior epigastric and following the free edge of the lacunar ligament to the obturator foramen.

piriform and coccygeus muscles. It then crosses the ischial spine and courses through the medial part of the lesser sciatic foramen to enter a tunnel deep to the fascia of the obturator internus muscle called the pudendal canal (of Alcock<sup>1</sup>). At this point the obturator internus forms the lateral wall of the ischiorectal fossa, and the canal courses about 4 cm above the lower margin of the ischial tuberosity. The artery gradually approaches the margin of the inferior ramus of the ischium, and then passes ventrally between the two layers of the fascia of the urogenital diaphragm. Continuing anteriorly along the medial margin of the inferior ramus of the pubis and about 1.25 cm dorsal

to the arcuate pubic ligament, it divides into the **dorsal** and **deep arteries of the penis**, but it may pierce the superficial fascia of the urogenital diaphragm before doing so (Fig. 8-68).

**RELATIONS OF THE MALE INTERNAL PUDENDAL ARTERY.** Within the pelvis, the internal pudendal artery lies anterior to the piriformis muscle, the sacral plexus of nerves, and the inferior gluteal artery. Crossing the ischial spine, it is covered by the gluteus maximus and overlapped by the sacrotuberous ligament. At this latter side, the pudendal nerve lies medial to the artery, and the nerve to the obturator internus muscle lies lateral to the artery. In the perineum, the internal pudendal artery lies on the lateral wall of the ischiorectal fossa in the pudendal canal, formed by the splitting of the obturator fascia. It is accompanied by a pair of companion veins and the pudendal nerve.

<sup>1</sup>Benjamin Alcock (1801-unknown): An Irish anatomist who moved to America in 1855.

FIG. 8-68. The superficial branches of the internal pudendal artery in the male urogenital region.

**BRANCHES OF THE MALE INTERNAL PUDENDAL ARTERY.** Although a few muscular branches arise from the internal pudendal artery within the pelvis, most branches supply structures in both the anal and the urogenital regions of the perineum. The branches are:

- Muscular
- Inferior rectal
- Perineal
- Artery of the bulb of the penis
- Urethral
- Deep artery of the penis
- Dorsal artery of the penis

**MUSCULAR BRANCHES.** Muscular branches from the internal pudendal artery consist of two sets: one given off in the pelvis and the other as the vessel crosses the ischial spine in the gluteal region. Within the pelvis several small unnamed vessels supply the levator ani, the obturator internus, the piriformis, and the coccygeus. The branches given off in the gluteal region are distributed to the adjacent parts of the gluteus maximus and to other lateral rotator muscles; they anastomose with branches of the inferior gluteal artery.

**INFERIOR RECTAL ARTERY.** Also known as the *inferior hemorrhoidal artery*, this vessel arises from the internal pudendal as it passes above the ischial tuberosity. Piercing the fascial sheath forming the pudendal canal, the artery divides into two or three branches which cross the ischiorectal fossa and are distributed to the muscles and integument of the anal region (Fig. 8-68). Small branches also ascend around the lower edge of the gluteus maximus to the skin of the buttock. Branches of the inferior rectal artery anastomose with the corresponding vessels of the opposite side, with the superior and middle rectal, and with the perineal artery.

**PERINEAL ARTERY.** The perineal artery arises from the internal pudendal anterior to the inferior rectal branches. It pierces the urogenital diaphragm and crosses either over or under the superficial transverse perineal muscle (Fig. 8-68). Continuing forward in the superficial perineal compartment of the urogenital region, the vessel courses anteriorly, parallel to the pubic arch, in the interspace between the bulbospongiosus and ischiocavernosus muscles. It supplies both these muscles and finally divides into several **posterior scrotal branches**, which are

distributed to the skin and dartos tunic of the scrotum. As it pierces the urogenital diaphragm, the perineal artery gives off a small **transverse branch**, which courses medially along the cutaneous surface of the superficial transverse perineal muscle and anastomoses with the corresponding vessel of the opposite side and with the inferior rectal arteries. The transverse branch supplies the muscle and other structures between the anus and the bulb of the penis.

**ARTERY OF THE BULB OF THE PENIS.** The artery to the bulb is a short vessel of large caliber which arises from the internal pudendal between the two layers of fascia of the urogenital diaphragm (Fig. 8-68). It passes medially, pierces the inferior fascia of the urogenital diaphragm, and gives off branches that ramify in the bulb of the penis and in the posterior part of the corpus spongiosum penis. It gives off a small branch to the **bulbourethral gland** (of Cowper<sup>1</sup>).

**URETHRAL ARTERY.** The urethral branch of the internal pudendal artery arises a short distance anterior to the artery of the bulb of the penis. It runs medially, pierces the inferior fascia of the urogenital diaphragm, and enters the corpus spongiosum penis in which it is continued forward to the glans penis. It supplies the urethra and its surrounding tissue.

**DEEP ARTERY OF THE PENIS.** The deep artery of the penis is one of the terminal branches of the internal pudendal artery (Fig. 8-68). It arises from that vessel while it is situated between the two fascial layers of the urogenital diaphragm. It pierces the inferior fascial layer of the urogenital diaphragm and enters the crus penis obliquely. The deep artery continues distally in the center of the corpus cavernosum penis, its branches being distributed to the erectile tissue.

**DORSAL ARTERY OF THE PENIS.** The dorsal artery of the penis is the other terminal branch of the internal pudendal artery (Fig. 8-68). It arises in the deep perineal compartment, just lateral and deep to the bulbospongiosus muscle. Piercing the inferior fascia of the urogenital diaphragm between the crus penis and the pubic arch, it then passes between the two layers of the suspensory ligament to reach the dorsum of the penis,

<sup>1</sup>William Cowper (1666-1709): An English surgeon and anatomist (London).

where it runs distally to the glans, sending branches to the glans and prepuce. Along the penis, it lies between the dorsal nerve and deep dorsal vein. It supplies the skin and fibrous sheath of the corpora cavernosa penis and anastomoses with the deep artery.

**VARIATIONS OF THE MALE INTERNAL PUDENDAL ARTERY.** Sometimes the internal pudendal artery is smaller than usual or fails to give off one or two of its usual branches. In such instances, the deficiency generally is supplied by branches derived from an additional vessel, the **accessory pudendal artery**, which usually arises from the internal pudendal artery before its exit from the greater sciatic foramen. The accessory vessel passes forward along the lower part of the bladder and across the side of the prostate to the root of the penis, where it perforates the urogenital diaphragm, and gives off branches usually derived from the internal pudendal artery. The variation most frequently encountered is that in which the internal pudendal ends as the artery of the urethral bulb, while the dorsal and deep arteries of the penis arise from the accessory pudendal. The internal pudendal artery may also end as the perineal artery, the artery of the urethral bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudendal artery is derived from one of the other branches of the internal iliac artery, most frequently the inferior vesical or the obturator.

#### Internal Pudendal Artery in the Female

In the female, the internal pudendal artery is considerably smaller than in the male. Its origin and course, however, are similar and there are comparable branches for the homologous structures. **Posterior labial branches** of the perineal artery supply the labia majora; the **artery of the bulb** supplies the erectile tissue of the vestibular bulb and the vagina; the **deep artery of the clitoris** supplies the corpus cavernosum clitoridis; and the **dorsal artery of the clitoris** supplies the dorsum of that organ, ending in the glans and prepuce of the clitoris.

#### ILIOLUMBAR ARTERY

The iliolumbar artery is a branch of the internal iliac artery, which usually comes off the posterior trunk (Figs. 8-64; 8-65). It courses upward and laterally beneath the common iliac artery, initially between the lumbosacral trunk and the obturator nerve. It then ascends between the vertebral col-

umn and the psoas major muscle. Just above the pelvic brim and behind the psoas major muscle, the iliolumbar artery divides into a **lumbar** and an **iliac branch**.

**LUMBAR BRANCH.** The lumbar branch of the iliolumbar artery supplies the psoas major and quadratus lumborum, and anastomoses with the fourth, which is the last, lumbar artery. It also sends a small **spinal branch** through the intervertebral foramen between the last lumbar vertebra and the sacrum, into the vertebral canal, to supply the cauda equina of the spinal cord.

**ILIAC BRANCH.** The iliac branch of the iliolumbar artery descends to supply the iliacus muscle. Some branches, running between the muscle and the bone, anastomose with the iliac branches of the obturator artery. One of these enters an oblique canal to supply the ilium, while others run along the crest of the ilium, distributing branches to the gluteal and abdominal muscles, and anastomosing in their course with the superior gluteal, the circumflex iliac, and the lateral femoral circumflex arteries.

#### LATERAL SACRAL ARTERIES

The lateral sacral arteries arise from the posterior trunk of the internal iliac; there are usually two, a **superior** and an **inferior** (Figs. 8-64; 8-65).

**SUPERIOR LATERAL SACRAL ARTERY.** The superior lateral sacral artery passes medially and, after anastomosing with branches from the middle sacral, enters the first or second pelvic (anterior) sacral foramen. It supplies branches to the contents of the sacral canal and anastomoses with other spinal vessels. It then leaves the spinal canal by passing through the corresponding posterior sacral foramen, and is distributed to the skin and muscles on the dorsum of the sacrum, anastomosing with the superior gluteal artery.

**INFERIOR LATERAL SACRAL ARTERY.** The inferior lateral sacral artery courses obliquely across the piriformis muscle and the anterior rami of the sacral nerves to the medial side of the pelvic (anterior) sacral foramina. It descends on the sacrum and anastomoses over the coccyx with the middle sacral and the opposite lateral sacral artery. In its course, it gives off branches that enter the pelvic sacral foramina. After supplying the contents of the sacral canal, these vessels emerge through the posterior sacral foram-

ina and are distributed to the muscles and skin on the dorsal surface of the sacrum. They anastomose with both the superior and inferior gluteal arteries.

### SUPERIOR GLUTEAL ARTERY

The superior gluteal artery is the largest branch of the internal iliac artery and is a direct continuation of its posterior trunk (Figs. 8-64; 8-65; 8-74; 8-76). It is a short artery that courses backward between the lumbosacral trunk and the first sacral nerve. Passing out of the pelvis through the greater sciatic foramen, above the superior border of the piriformis muscle, the superior gluteal artery immediately divides into a **superficial branch** and a **deep branch** (Fig. 8-69). Within the pelvis it gives off muscular branches to the iliacus, piriformis, and obturator internus, and before leaving that cavity, it gives off a nutrient artery which enters the ilium.

**SUPERFICIAL BRANCH.** The superficial branch of the superior gluteal artery enters

the deep surface of the gluteus maximus and divides into numerous branches (Fig. 8-69). Some of these supply the muscle and anastomose with the inferior gluteal artery; others perforate its tendinous origin and supply the skin covering the dorsal surface of the sacrum, anastomosing with the posterior branches of the lateral sacral arteries.

**DEEP BRANCH.** The deep branch of the superior gluteal artery lies deep to the gluteus medius and almost immediately subdivides into a superior and an inferior division (Fig. 8-69). The **superior division** continues the original course of the vessel and passes along the superior border of the gluteus minimus to the anterior superior spine of the ilium. It anastomoses with the deep iliac circumflex artery and the ascending branch of the lateral femoral circumflex artery. The **inferior division** crosses the gluteus minimus obliquely to the greater trochanter, distributing branches to the gluteal muscles and anastomosing with the lateral femoral circumflex artery. Some branches pierce the

**Fig. 8-69.** The superior and inferior gluteal arteries and their branches. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 1975.)

gluteus minimus to supply the hip joint. Throughout most of its course, the deep branch of the superior gluteal artery ramifies between the gluteus medius and gluteus minimus muscles, helping to define the plane of separation between their fibers.

### INFERIOR GLUTEAL ARTERY

The inferior gluteal artery is distributed chiefly to the buttocks and back of the thigh. It passes posteriorly between the first and second sacral nerves, or between the second and third sacral nerves, and then descends between the piriformis and coccygeus muscles through the lower part of the greater sciatic foramen to the gluteal region (Figs. 8-64; 8-65; 8-74; 8-76). It then descends in the interval between the greater trochanter of the femur and tuberosity of the ischium, accompanied by the sciatic and posterior femoral cutaneous nerves and covered by the gluteus maximus. The inferior gluteal artery continues down the posterior thigh, supplying the skin and anastomosing with vessels from the perforating branches of the femoral artery.

#### Branches of the Inferior Gluteal Artery

Within the pelvis, the inferior gluteal artery distributes branches to the piriformis, coccygeus, and levator ani. Some branches help to supply the fat around the rectum, and occasionally take the place of the middle rectal artery. Other branches help to supply the fundus of the bladder, the seminal vesicles, and the prostate.

Outside the pelvis (Fig. 8-69), the inferior gluteal artery gives off the following branches:

- Muscular
- Coccygeal
- Artery of the sciatic nerve
- Anastomotic
- Articular
- Cutaneous

**MUSCULAR BRANCHES.** Muscular branches from the inferior gluteal artery in the gluteal region supply (1) the gluteus maximus, where they anastomose with the superior gluteal artery in the substance of the muscle; (2) the smaller, lateral rotator muscles, anastomosing with the internal pudendal artery;

and (3) the upper part of the hamstring muscles attached to the tuberosity of the ischium. These latter vessels anastomose with the posterior branch of the obturator and the medial femoral circumflex arteries.

**COCYGEAL BRANCHES.** The coccygeal branches course medially, pierce the sacrotuberous ligament, and supply the gluteus maximus, the skin, and other structures on the back of the coccyx (Fig. 8-76).

**ARTERY OF THE SCIATIC NERVE.** This long, slender branch of the inferior gluteal artery accompanies the sciatic nerve for a short distance, then penetrates it and runs in its substance to the distal part of the thigh (Fig. 8-69).

**ANASTOMOTIC BRANCH.** The anastomotic branch of the inferior gluteal artery descends obliquely and laterally in the gluteal region across the small external rotators of the thigh to assist in forming the so-called **cruciate anastomosis**. This anastomosis around the neck and greater trochanter of the femur involves the first perforating and medial and lateral femoral circumflex branches of the femoral artery in addition to the inferior gluteal artery.

**ARTICULAR BRANCH.** An articular branch, generally arising from the anastomotic, is distributed to the capsule of the hip joint.

**CUTANEOUS BRANCHES.** The cutaneous branches of the inferior gluteal artery are distributed to the skin of the buttock and posterior thigh.

### External Iliac Artery

The external iliac artery on both the right and left sides is larger than the internal iliac. Each vessel passes obliquely downward and laterally along the medial border of the psoas major muscle. The external iliac artery extends from the bifurcation of the common iliac artery to a point beneath the inguinal ligament, midway between the anterior superior spine of the ilium and the symphysis pubis (Figs. 8-64; 8-65; 8-70; 8-74). Entering the thigh below the inguinal ligament, the vessel then becomes the **femoral artery**.

**RELATIONS.** Anteriorly and medially, the external iliac artery is related to the parietal peritoneum, the subperitoneal areolar tissue, the termination of the

ileum, and, frequently, the vermiform appendix on the right side and the sigmoid colon on the left side. The origin of the artery is occasionally crossed by the ureter and, in females, by the ovarian artery and vein. The testicular vessels lie for some distance on the external iliac artery above the inguinal ligament, but near its termination. The vessel is crossed at this site by the genital branch of the genitofemoral nerve and the deep iliac circumflex vein. Curving across its medial aspect in the male is the ductus deferens, or in the female, the round ligament of the uterus. *Posteriorly*, the external iliac artery is related to the medial border of the psoas major muscle, from which it is separated by the iliac fascia. Proximally, the lateral portion of the external iliac vein lies behind the artery, but more distally, the vein courses entirely medial to the artery. *Laterally*, the external iliac artery rests on the iliac fascia overlying the psoas major muscle. Numerous lymphatic vessels and lymph nodes lie on the anterior and medial aspects of the vessel.

**COLLATERAL CIRCULATION.** The principal anastomoses providing collateral circulation after the application of a ligature to the external iliac are: (1) the iliolumbar with the iliac circumflex, (2) the superior gluteal with the lateral femoral circumflex, (3) the obturator with the medial femoral circumflex, (4) the inferior gluteal with the first perforating and circumflex branches of the profunda artery, and (5) the internal pudendal with the external pudendal. When the obturator artery arises from the inferior epigastric, it receives blood by branches from the internal iliac or the lateral sacral or the internal pudendal artery, and the inferior epigastric receives blood by anastomoses with the internal thoracic and lower intercostal arteries, and from the internal iliac by anastomoses of its branches with the obturator.

### Branches of the External Iliac Artery

In addition to several small branches given to the psoas major muscle and the neighboring lymph nodes, the external iliac gives off two branches of considerable size. These are the:

Inferior epigastric  
Deep iliac circumflex

### INFERIOR EPIGASTRIC ARTERY

The inferior epigastric artery arises from the external iliac immediately above the inguinal ligament (Figs. 8-70; 8-74). It curves anteriorly in the subperitoneal tissue and then ascends obliquely along the medial margin of the deep inguinal ring. Continuing its course upward, the vessel pierces the transversalis fascia, and passing anterior to the arcuate line, it ascends between the rectus abdominis muscle and the posterior layer of its sheath. The inferior epigastric artery finally divides into numerous branches, and these anastomose, above the umbilicus, with the superior epigastric branch of the internal thoracic and with the lower posterior intercostal arteries (see Fig. 8-31). As the inferior epigastric artery passes obliquely upward from its origin, it lies along the lower and medial margins of the

**FIG. 8-70.** The inferior epigastric artery seen from the inner aspect of the lower abdominal wall. Observe also the relationships of the femoral ring and the deep inguinal ring.

deep inguinal ring and behind the commencement of the spermatic cord. The ductus deferens in the male or the round ligament of the uterus in the female winds around the lateral and dorsal aspects of the artery. In its ascent on the inner aspect of the anterior abdominal wall, it is covered by a reflection of peritoneum called the **lateral umbilical fold**. The following branches arise from the inferior epigastric artery:

Cremasteric  
Artery of the round ligament  
Pubic  
Muscular

**CREMASTERIC ARTERY.** The cremasteric artery is found in males and it accompanies the spermatic cord, supplying the cremaster muscle and other coverings of the cord. It anastomoses with the testicular, the external pudendal, and the perineal arteries.

**ARTERY OF THE ROUND LIGAMENT.** In females, the artery that corresponds to the cremasteric is a small vessel that accompanies the round ligament of the uterus.

**PUBIC BRANCH.** The pubic branch of the inferior epigastric artery courses along the inguinal ligament. It then descends along the medial margin of the femoral ring to the internal surface of the pubis and there anastomoses with the pubic branch of the obturator artery. In almost one-third of the cadavers, the pubic branch is much larger and actually becomes the obturator artery.

**MUSCULAR BRANCHES.** Some of the muscular branches of the inferior epigastric artery are distributed to the abdominal muscles and peritoneum, anastomosing with the iliac circumflex and lumbar arteries. Other branches perforate the tendon of the external oblique muscle to supply the skin and to anastomose with branches of the superficial epigastric artery.

**VARIATIONS.** The inferior epigastric artery may arise from any part of the external iliac between the inguinal ligament and a point 6 cm above it. The vessel may also arise from the femoral artery below the inguinal ligament. Frequently it branches from the external iliac by a common trunk with the obturator. Sometimes the inferior epigastric arises from the obturator, the latter vessel being furnished by the internal iliac, or it may be formed by two branches, one derived from the external iliac, the other from the internal iliac.

## DEEP ILIAC CIRCUMFLEX ARTERY

The deep iliac circumflex artery arises from the lateral aspect of the external iliac almost opposite the inferior epigastric artery (Fig. 8-74). It ascends laterally to the anterior superior iliac spine, deep to the inguinal ligament. In its course it lies between the transversalis fascia and the peritoneum, or it is contained in a fibrous sheath formed by the union of the transversalis fascia and iliac fascia. In the lateral wall of the pelvis, the deep iliac circumflex artery anastomoses with the ascending branch of the lateral femoral circumflex artery from below. It then pierces the transversalis fascia and passes along the inner lip of the crest of the ilium to about its middle, where it perforates the transversus abdominis, and runs dorsally between that muscle and the internal oblique to anastomose with the iliolumbar and superior gluteal arteries. Opposite the anterior superior iliac spine, it gives off a large **ascending branch**, which courses between the internal oblique and transversus muscles, supplying them and anastomosing with the lumbar and inferior epigastric arteries.

## Arteries of the Lower Limb

The artery that supplies the greater part of the lower limb is the direct continuation of the external iliac (Fig. 8-74). It courses as a single trunk from the inguinal ligament to the lower border of the popliteus muscle behind the knee joint, where it divides into two branches, the **anterior** and **posterior tibial**. The upper part of the main trunk courses through the anterior and medial aspect of the thigh and is called the **femoral artery**. Below the adductor canal, the artery passes through a hiatus in the tendon of the adductor magnus muscle in order to reach the popliteal fossa, where the vessel is called the **popliteal artery**.

### Femoral Artery

The femoral artery, being the continuation of the external iliac artery, begins immediately below the inguinal ligament, midway

FIG. 8-71. Femoral sheath opened to show its three compartments.

between the anterior superior iliac spine and the symphysis pubis (Figs. 8-71 to 8-75). It passes distally along the anteromedial aspect of the thigh, ending at the junction of the middle and lower thirds of the thigh, where it passes through an opening in the tendon of the adductor magnus muscle to become the **popliteal artery** (Fig. 8-76). In the upper part of the thigh, the femoral artery lies anterior to the hip joint, while in the lower part of its course, it lies medial to the shaft of the femur. Between these two parts, it crosses the angle between the head and shaft, remaining at some distance from the bone. The first 4 cm of the vessel are enclosed, together with the femoral vein, in the fibrous **femoral sheath**. In the upper third of the thigh, the femoral artery is contained in the **femoral triangle** (of Scarpa<sup>1</sup>) and in the

middle third of the thigh, in the **adductor canal** (of Hunter<sup>2</sup>).

**FEMORAL SHEATH.** The femoral sheath is formed by a prolongation downward under the inguinal ligament of the transversalis fascia anterior to the femoral vessels and the iliac fascia behind them (Figs. 8-71; 8-72). The sheath assumes the form of a short funnel, the wide end of which is directed superiorly, while the inferior, narrow end fuses with the adventitia of the vessels, about 4 cm below the inguinal ligament. It is strengthened anteriorly by a band termed the **deep crural arch**. The *lateral wall* of the sheath is perforated by the femoral branch of the genitofemoral nerve. The *medial wall* is pierced by the great saphenous vein and by some lymphatic vessels. The sheath is divided into three compartments by two verti-

FIG. 8-72. The structures passing deep to the inguinal ligament, as seen inferiorly.

cal partitions which stretch between its anterior and posterior walls. The *lateral compartment* contains the femoral artery, and the *intermediate compartment* contains the femoral vein. The *medial compartment* is the smallest and is called the **femoral canal** (Figs. 8-71; 8-72). It contains some lymphatic vessels and a lymph node (of Cloquet<sup>1</sup> or Rosenmüller<sup>2</sup>) embedded in a small amount of areolar tissue. The femoral canal is conical and measures about 1.25 cm in length. Its base is directed superiorly and, although oval in form, is named the **femoral ring** (Fig. 8-70). The long diameter of the ring is directed transversely and it measures about 1.25 cm. The femoral ring (Fig. 8-70) is bounded anteriorly by the inguinal ligament, posteriorly by the pectineus muscle and its overlying pectineal fascia, medially by the crescentic base of the lacunar ligament, and laterally by the fibrous septum on the medial aspect of the femoral vein. The spermatic cord in the male and the round ligament of the uterus in the female lie immediately superior to the anterior margin of the ring, and the inferior epigastric vessels

are close to its superior and lateral angle (Fig. 8-70). The femoral ring is closed by a somewhat condensed portion of the subperitoneal fatty tissue, called the **femoral septum**, the abdominal surface of which supports a small lymph node and is covered by the parietal layer of the peritoneum. The peritoneum presents a slight depression named the **femoral fossa**. The femoral septum is pierced by numerous lymphatic vessels passing from the deep inguinal to the external iliac lymph nodes. The femoral nerve is not enclosed by the femoral sheath (Fig. 8-71).

**FEMORAL TRIANGLE.** The femoral triangle corresponds to the depression seen immediately below the fold of the groin (Fig. 8-73). Its **apex** is directed inferiorly, and the **sides** are formed laterally by the sartorius, medially by the adductor longus, and superiorly by the inguinal ligament. The **floor** of the space is formed from its lateral to medial aspect by the iliacus, psoas major, and pectineus muscles, and in some cases by a small part of the adductor brevis. It is divided into two nearly equal parts by the femoral vessels, which extend from near the middle of its base to its apex. The femoral artery gives off both its more superficial and deep branches, while the femoral vein receives its femoral and great saphenous tributaries. On the lateral aspect of the femoral artery is the

<sup>1</sup>Jules G. Cloquet (1790-1883): A French anatomist and surgeon (Paris).

<sup>2</sup>Johann C. Rosenmüller (1771-1820): A German anatomist (Leipzig).

**Fig. 8-73.** The left femoral vessels and some of their branches, and the femoral nerve in the femoral triangle.

femoral nerve and its branches. In addition to the vessels and nerves, the femoral triangle contains some fat and lymphatics.

**ADDUCTOR CANAL.** The adductor canal is a fascial tunnel in the middle third of the thigh, extending from the apex of the femoral triangle to the opening in the tendon of the adductor magnus muscle, through which the femoral vessels course to the popliteal fossa (Figs. 8-75; 8-76). The canal is bounded anteriorly and laterally by the vastus medialis muscle, and posteriorly by the adductors longus and magnus. It is covered anteriorly by a strong fascia that lies deep to the sartorius and extends from the vastus medialis across the femoral vessels to the adductors longus and magnus. The canal contains the femoral artery and vein, and the saphenous nerve.

**RELATIONS OF THE FEMORAL ARTERY.** In the **femoral triangle**, the artery is situated quite superficially. *Anterior* to it are the skin, the superficial fascia, the superficial inguinal lymph nodes, the superficial iliac circumflex vein, the superficial layer of the fascia lata, and the anterior part of the femoral sheath. The femoral branch of the genitofemoral nerve courses for a short distance within the lateral compartment of the femoral sheath and lies at first lateral and then anterior to the artery. Near the apex of the femoral triangle, the medial cutaneous branches of the femoral nerve cross the artery from its lateral to its medial aspect.

*Posterior* to the femoral artery are the posterior part of the femoral sheath, the pectineal fascia, the medial part of the tendon of the psoas major muscle, the pectineus muscle, and the adductor longus muscle. The artery is separated from the capsule of the hip joint by the tendon of the psoas major muscle, from the pectineus muscle by the femoral vein and

deep femoral vessels, and from the adductor longus muscle by the femoral vein. The nerve to the pectineus passes medially behind the artery. On the *lateral aspect* of the artery, but separated from it by some fibers of the psoas major muscle, is the femoral nerve. The femoral vein is on the *medial aspect* of the artery in the upper part of the femoral triangle, but is posterior to it in the lower part of the triangle.

In the **adductor canal** (Fig. 8-75), the femoral artery is more deeply situated, being covered by the skin, the superficial and deep fasciae, the sartorius, and the fibrous roof of the femoral canal. The saphenous nerve crosses the artery from its lateral to its medial aspect within the adductor canal. *Posterior* to the artery are the adductors longus and magnus, and *anterolateral* to it is the vastus medialis. The femoral vein lies behind the artery in the upper part of the adductor canal, but lateral to it in the distal part of the canal.

**VARIATIONS.** In rare cases the femoral artery is absent, and its place is taken by an enlarged inferior gluteal artery, which has accompanied the sciatic nerve to the popliteal fossa. When this occurs, the inferior gluteal represents the persistence of the original axis artery (Fig. 8-13), and the external iliac is small, terminating as the deep femoral artery. Occasionally, the femoral vein courses along the medial aspect of the artery throughout the entire extent of the femoral triangle, or it may be split so that a large vein is placed on both sides of the artery for a greater or lesser distance through the thigh.

**COLLATERAL CIRCULATION.** After ligation of the femoral artery, collateral circulation (Fig. 8-74) results from anastomoses of (1) the superior and inferior gluteal branches of the internal iliac with the medial and lateral femoral circumflex and first perforating branches of the deep femoral artery; (2) the obturator branch of the internal iliac with the medial femoral circumflex branch of the deep femoral; (3) the internal pudendal from the internal iliac with the superficial and deep external pudendal arteries off the femoral; (4) the deep iliac circumflex from the external iliac with the lateral femoral circumflex of the deep femoral and the superficial iliac circumflex of the femoral; and (5) the inferior gluteal of the internal iliac with the perforating branches of the deep femoral artery (Fig. 8-76).

#### Branches of the Femoral Artery

The branches of the femoral artery are:

- Superficial epigastric
- Superficial circumflex iliac
- Superficial external pudendal
- Deep external pudendal
- Muscular
- Profunda femoris
- Descending genicular artery

#### SUPERFICIAL EPIGASTRIC ARTERY

The superficial epigastric artery arises from the femoral artery about 1 cm below the inguinal ligament (Figs. 8-73; 8-75). It passes through the femoral sheath and the cribriform fascia, turns upward in front of the inguinal ligament, and ascends between the two layers of the superficial fascia, anterior to the external oblique muscle of the abdominal wall, almost to the umbilicus. It distributes branches to the superficial subinguinal lymph nodes, the superficial fascia, and the skin. It anastomoses with branches of the inferior epigastric artery and with the superficial epigastric of the other side.

#### SUPERFICIAL CIRCUMFLEX ILIAC ARTERY

The superficial circumflex iliac artery is the smallest of the superficial branches of the femoral artery. It arises close to the superficial epigastric, pierces the fascia lata, runs laterally, parallel to the inguinal ligament, to the crest of the ilium (Figs. 8-73; 8-75). It divides into branches that supply the skin of the groin and the superficial subinguinal lymph nodes, and it anastomoses with the deep circumflex iliac, superior gluteal, and lateral femoral circumflex arteries.

#### SUPERFICIAL EXTERNAL PUDENDAL ARTERY

The superficial external pudendal artery arises from the medial aspect of the femoral artery, close to the preceding vessels (Figs. 8-73; 8-75). After piercing the femoral sheath and the cribriform fascia, it courses medially across the spermatic cord (or round ligament in the female) and is distributed to the skin on the lower part of the abdomen, and to the penis and scrotum in the male, or the labium majus in the female. It anastomoses with branches of the internal pudendal artery.

#### DEEP EXTERNAL PUDENDAL ARTERY

The deep external pudendal artery, more deeply situated than the preceding vessel, passes medially across the pectineus and adductor longus muscles (Figs. 8-73; 8-75). It is covered by the fascia lata, which it pierces at the medial aspect of the thigh, and is dis-

**Fig. 8-74.** Collateral circulation about the hip and the upper part of the right thigh. (From Eycleshymer and Jones.)

tributed to the skin of the scrotum and perineum in the male or to the labium majus in the female. Its branches anastomose with the posterior scrotal (or labial) branches of the perineal artery.

#### MUSCULAR BRANCHES

Muscular branches of the femoral artery supply the sartorius, vastus medialis, and adductor muscles.

#### DEEP FEMORAL ARTERY

The deep (or profunda) femoral artery is a large vessel that arises from the lateral and posterior part of the femoral artery, 2 to 5 cm below the inguinal ligament (Figs. 8-74; 8-75). Initially, it lies lateral to the femoral artery, but then courses behind it and the femoral vein to the medial aspect of the femur. Passing down to the lower third of the thigh, posterior to the adductor longus muscle, the deep femoral artery ends as a small branch.

arose from 2.25 to 5 cm below the inguinal ligament. In a few specimens it arose higher, more rarely opposite the inguinal ligament, and in one subject, above the ligament from the external iliac artery. Occasionally the distance between the origin of the deep femoral artery and the inguinal ligament exceeds 5 cm.

#### Branches of the Deep Femoral Artery

The deep femoral artery supplies much of the musculature in the anterior and medial compartments of the thigh. Some of its vessels penetrate through the musculature to the posterior compartment, thereby contributing to the supply of the hamstrings. Its branches are:

- Medial femoral circumflex
- Lateral femoral circumflex
- Perforating
- Muscular

#### Medial Femoral Circumflex Artery

The medial femoral circumflex artery arises from the medial aspect of the deep femoral and winds around the medial aspect of the femur (Fig. 8-74). In about 25% of cadavers it arises directly from the femoral artery. It passes first between the pectineus and psoas major muscles, and then between the obturator externus and the adductor brevis. Continuing into the gluteal region between the quadratus femoris and adductor magnus muscles, it gives off ascending and transverse branches. The **ascending branch** goes to the adductor muscles, the gracilis, and the obturator externus, and it anastomoses with the obturator artery. The **transverse branch** descends beneath the adductor brevis to supply it and the adductor magnus.

The continuation of the medial femoral circumflex artery passes posteriorly and divides into superficial, deep, and acetabular branches. The **superficial branch** appears between the quadratus femoris and the proximal border of the adductor magnus. It anastomoses with the inferior gluteal, lateral femoral circumflex, and first perforating arteries, thereby contributing to the cruciate anastomosis. The **deep branch** runs obliquely upward upon the tendon of the obturator externus, and in front of the quadratus

femoris toward the trochanteris fossa, where it anastomoses with twigs from the gluteal arteries. The **acetabular branch** arises opposite the acetabular notch and enters the hip joint beneath the transverse acetabular ligament in company with the acetabular branch of the obturator artery. It supplies the fat in the acetabular fossa and continues along the round ligament to the head of the femur.

#### Lateral Femoral Circumflex Artery

The lateral femoral circumflex artery arises from the lateral aspect of the deep femoral artery (Figs. 8-74; 8-75). In nearly 20% of cadavers studied, it arises independently from the femoral artery. It passes laterally between the divisions of the femoral nerve and behind the sartorius and rectus femoris muscles, and divides into ascending, transverse, and descending branches.

The **ascending branch** passes superiorly, deep to the tensor fasciae latae, to the lateral aspect of the hip, and anastomoses with the terminal branches of the superior gluteal and deep iliac circumflex arteries.

The **descending branch** of the lateral femoral circumflex artery courses downward behind the rectus femoris and upon the vastus lateralis, which it supplies. One long branch descends in the vastus lateralis muscle as far as the knee and anastomoses with the superior lateral genicular branch of the popliteal artery. It is accompanied by the branch of the femoral nerve to the vastus lateralis.

The **transverse branch** is the smallest branch, but it is often absent. It passes laterally over the vastus intermedius, pierces the vastus lateralis, and winds around the femur, just below the greater trochanter. It anastomoses on the back of the thigh with the medial femoral circumflex, inferior gluteal, and first perforating arteries, thereby participating in the cruciate anastomosis.

#### Perforating Arteries

Usually three perforating arteries arise from the deep femoral artery, and the termination of the deep femoral is frequently considered the fourth (Figs. 8-74; 8-76). These vessels are so named because they perforate the adductor magnus muscle to reach the

Fig. 8-76. The arteries of the gluteal, posterior femoral, and popliteal regions.

back of the thigh. They pass posteriorly close to the linea aspera of the femur under cover of the small tendinous arches in the muscle. The first is given off above the adductor brevis, the second anterior to that muscle, and the third immediately below it.

The **first perforating artery** passes posteriorly between the pectineus and adductor brevis muscles, and sometimes it perforates the latter (Figs. 8-74; 8-76). It then pierces the adductor magnus close to the linea aspera, giving branches to the adductors brevis and magnus, the biceps femoris, and the gluteus maximus. It anastomoses with the infer-

ior gluteal, medial and lateral femoral circumflex, and second perforating arteries (Fig. 8-74).

The **second perforating artery**, larger than the first, pierces the tendons of the adductors brevis and magnus and divides into ascending and descending branches, which supply the posterior femoral muscles and anastomose with the first and third perforating (Fig. 8-76). The second perforating artery frequently arises in common with the first. The **nutrient artery of the femur** usually branches from the second perforating artery, but when two nutrient arteries exist, they

usually are derived from the first and third perforating vessels.

The **third perforating artery** pierces the adductor magnus and divides into branches that supply the posterior femoral muscles (Fig. 8-76). These anastomose above with the higher perforating arteries and below with the terminal branches of the deep femoral artery and the muscular branches of the popliteal. The termination of the deep femoral artery, as was already described, is sometimes termed the **fourth perforating artery**.

### Muscular Branches

Numerous muscular branches arise from the deep femoral artery. Some of these end in the adductor muscles; others pierce the adductor magnus, give branches to the hamstrings, and anastomose with the medial femoral circumflex artery and with the superior muscular branches of the popliteal artery.

### DESCENDING GENICULAR ARTERY

The descending genicular artery arises from the femoral just before the latter vessel passes through the opening in the tendon of the adductor magnus muscle (Figs. 8-74; 8-75). It immediately divides into a saphenous and an articular branch.

**SAPHENOUS BRANCH.** The saphenous branch of the descending genicular artery pierces the aponeurotic covering of the adductor canal and accompanies the saphenous nerve to the medial aspect of the knee. It passes between the sartorius and gracilis muscles and, piercing the fascia lata, is distributed to the skin on the upper and medial part of the leg. It anastomoses with the medial inferior genicular artery.

**ARTICULAR BRANCH.** The articular branch of the descending genicular artery descends in the substance of the vastus medialis, anterior to the tendon of the adductor magnus, to the medial aspect of the knee (Fig. 8-75). Here it anastomoses with the medial superior genicular artery and anterior recurrent tibial artery. Another anastomosing branch crosses the lower thigh above the patellar surface of the femur, forming an arterial arch with the lateral superior genicular artery, from which branches supply the knee joint.

### Popliteal Artery

The popliteal artery is the continuation of the femoral artery and it courses through the popliteal fossa (Figs. 8-76; 8-77; 8-81). The vessel commences at an opening in the aponeurosis of the adductor magnus muscle at the lower end of the adductor canal. Extending from the junction of the middle and distal thirds of the posterior thigh, the popliteal artery courses downward to the intercondylar fossa of the femur. It then continues distally to the lower border of the popliteus muscle, where it divides into **anterior and posterior tibial arteries**.

**POPLITEAL FOSSA.** The popliteal fossa is a diamond-shaped region posterior to the knee joint. *Laterally* it is bounded by the biceps femoris above, and by the plantaris and the lateral head of the gastrocnemius below. *Medially* it is limited by the semitendinosus and semimembranosus above, and by the medial head of the gastrocnemius below. The floor of the fossa is oriented anteriorly and is formed by the popliteal surface of the femur, the oblique popliteal ligament of the knee joint, the proximal end of the tibia, and the fascia covering the popliteus muscle. The fossa is covered posteriorly by the popliteal fascia, which is pierced by the small saphenous vein.

**Contents of the Popliteal Fossa.** The popliteal fossa contains the popliteal vessels, the tibial and the common peroneal nerves, the termination of the small saphenous vein, the distal part of the posterior femoral cutaneous nerve, the articular branch from the obturator nerve, a few small lymph nodes, and a considerable amount of fat. The **tibial nerve** descends through the middle of the fossa, lying most superficially beneath the deep fascia and crossing behind the popliteal vessels from lateral to medial. The **common peroneal nerve** descends laterally along the upper part of the fossa, close to the tendon of the biceps femoris. The popliteal vessels course along the floor of the fossa. The **popliteal artery** is closest to the bone, and the popliteal vein, coursing superficial to the artery, is interposed between it and the nerves. The two vessels are united by dense areolar tissue. The **popliteal vein** is a thick-walled vessel which at first is lateral to the artery and then crosses it posteriorly to gain its medial aspect below. Sometimes the vein is doubled and interconnected by short

transverse branches. In these instances, the artery courses between the veins. The **articular branch of the obturator nerve** descends upon the artery to the knee joint. The **popliteal lymph nodes**, six or seven in number, are embedded in the fat. One node lies beneath the popliteal fascia near the termination of the external saphenous vein, another between the popliteal artery and the back of the knee joint, while others are aligned along the popliteal vessels. Arising from the popliteal artery and passing at right angles are its **genicular branches**.

**RELATIONS OF THE POPLITEAL ARTERY.** *Anterior* to the artery from above downward are the popliteal surface of the femur (which is separated from the vessel by some fat), the back of the knee joint, and the fascia covering the popliteus muscle. *Posteriorly*, the vessel is overlapped by the semimembranosus above, and it is covered by the gastrocnemius and plantaris muscles below. In the middle part of its course, the artery is separated from the skin and fascia by fat, and it is crossed from lateral to medial by the tibial nerve and the popliteal vein, the vein being interposed between the nerve and the artery and closely adherent to the latter. On its *lateral aspect* above are the biceps femoris, the tibial nerve, the popliteal vein, and the lateral condyle of the femur; below are the plantaris and the lateral head of the gastrocnemius. On its *medial aspect* above are the semimembranosus and the medial condyle of the femur; below are the tibial nerve, the popliteal vein, and the medial head of the gastrocnemius.

**VARIATIONS.** Occasionally the popliteal artery divides into its terminal branches opposite the knee joint. The anterior tibial under these circumstances usually passes anterior to the popliteus. Sometimes the popliteal artery divides into anterior tibial and peroneal branches, the posterior tibial being wanting or very small. Occasionally it divides into three branches, the anterior and posterior tibial and the peroneal arteries.

#### Branches of the Popliteal Artery

In addition to its terminal branches, the popliteal artery gives rise to muscular, cutaneous, and genicular vessels, the latter forming an anastomosis around the knee. The branches are:

- Superior muscular
- Sural
- Cutaneous
- Medial superior genicular
- Lateral superior genicular

- Middle genicular
- Medial inferior genicular
- Lateral inferior genicular

#### SUPERIOR MUSCULAR BRANCHES

Two or three superior muscular branches arise from the proximal part of the popliteal artery and are distributed to the lower parts of the adductor magnus and hamstring muscles (Fig. 8-76). These anastomose with the terminal vessels from the deep femoral artery.

#### SURAL ARTERIES

The medial and lateral sural arteries are two large branches which are distributed to the gastrocnemius, soleus, and plantaris muscles of the calf (Figs. 8-77; 8-81). They arise from the popliteal artery opposite the knee joint.

#### CUTANEOUS BRANCHES

Cutaneous branches arise either from the popliteal artery or from some of its branches. They descend between the two heads of the gastrocnemius, and piercing the deep fascia, they are distributed to the skin of the back of the leg. One branch usually accompanies the small saphenous vein.

#### SUPERIOR GENICULAR ARTERIES

There are usually two superior genicular arteries. These arise one on each side of the popliteal artery and are therefore called medial and lateral superior genicular arteries. They wind around the femur, immediately proximal to its condyles, to the front of the knee joint.

**MEDIAL SUPERIOR GENICULAR ARTERY.** The medial superior genicular courses anterior to the semimembranosus and semitendinosus above the medial head of the gastrocnemius (Figs. 8-76 to 8-78). Passing deep to the tendon of the adductor magnus, it divides into two branches. One of these supplies the vastus medialis, anastomosing with the descending genicular and medial inferior genicular arteries; the other ramifies close to the surface of the femur, supplying it and the knee joint, and anastomosing with the lateral superior genicular artery. The medial supe-

FIG. 8-77. The popliteal, posterior tibial, and peroneal arteries. Right leg.

FIG. 8-78. The arterial anastomosis around the knee joint. Anterior view.

rior genicular artery is often small, with a resulting compensatory increase in the size of the descending genicular artery.

**LATERAL SUPERIOR GENICULAR ARTERY.** The lateral superior genicular courses above the lateral condyle of the femur, deep to the tendon of the biceps femoris, and divides into a superficial and a deep branch (Figs. 8-76; 8-78; 8-80; 8-81). The **superficial branch** supplies the vastus lateralis and anastomoses with the descending branch of the lateral femoral circumflex and the lateral inferior genicular arteries. The **deep branch** supplies the lower part of the femur and knee joint and forms an anastomotic arch across the anterior aspect of the joint with the descending genicular, the medial superior genicular, and the inferior genicular arteries.

#### MIDDLE GENICULAR ARTERY

The middle genicular artery is a small vessel that arises from the popliteal artery opposite the back of the knee joint (Fig. 8-76). It

pierces the oblique popliteal ligament and supplies the ligaments and synovial membrane on the interior of the knee joint.

#### INFERIOR GENICULAR ARTERIES

Two inferior genicular arteries arise from the popliteal artery below the knee joint. Under cover of the gastrocnemius muscle, one vessel branches from the medial aspect of the main vessel and the other from the lateral.

**MEDIAL INFERIOR GENICULAR ARTERY.** The medial inferior genicular artery is usually the larger of the two lower genicular vessels (Figs. 8-77 to 8-79; 8-81). It descends medially in an oblique direction along the proximal margin of the popliteus, to which it gives branches. It then passes below the medial condyle of the tibia, deep to the tibial collateral ligament of the knee. At the anterior border of this ligament, the vessel ascends to the anterior and medial aspects of the joint, to supply the upper end of the tibia and the

knee joint itself. It anastomoses with the lateral inferior and medial superior genicular arteries.

**LATERAL INFERIOR GENICULAR ARTERY.** The lateral inferior genicular courses laterally above the head of the fibula to the front of the knee joint, passing deep to the lateral head of the gastrocnemius, the fibular collateral ligament of the knee joint, and the tendon of the biceps femoris (Figs. 8-77 to 8-80). It ends by dividing into branches that anastomose with the medial inferior and lateral superior genicular arteries, the anterior and posterior tibial recurrent, and the circumflex fibular branch of the posterior tibial artery.

**ANASTOMOSIS AROUND THE KNEE JOINT.** An intricate network of vessels forms a superficial and deep plexus of arteries around the patella and on the contiguous ends of the femur and tibia (Figs. 8-78; 8-80). The **superficial plexus** is situated in the superficial fascia around the patella and forms three well-defined arches. One is found above the upper border of the patella, in the loose connective tissue over the quadriceps femoris muscle. The other two, distal to the patella, are situated in the fat deep to the ligamentum patellae. The **deep plexus** forms a close network of vessels which lies on the lower end of the femur and upper end of the tibia around their articular surfaces, sending numerous branches into the interior of the knee joint. The arteries that form this plexus are the two medial and the two lateral genicular branches of the popliteal, the descending genicular, the descending branch of the lateral femoral circumflex, the anterior and posterior tibial recurrent, and the circumflex fibular.

### **Anterior Tibial Artery**

The anterior tibial artery commences at the lower border of the popliteus muscle at the bifurcation of the popliteal artery (Figs. 8-77; 8-81). It passes anteriorly between the two heads of the tibialis posterior muscle and then through the aperture above the upper border of the interosseous membrane, to achieve the deep part of the front of the leg. Here the anterior tibial artery lies close to the medial aspect of the neck of the fibula. Descending on the anterior surface of the interosseous membrane, the vessel gradually approaches the tibia (Figs. 8-79; 8-80). In the

distal part of the leg it lies on the tibia, and then anterior to the ankle joint, it becomes more superficial and is called the **dorsalis pedis artery**.

**RELATIONS OF THE ANTERIOR TIBIAL ARTERY.** In the upper two-thirds of its course, the anterior tibial artery rests upon the interosseous membrane. The lower one-third of the artery descends upon the front of the tibia and the anterior ligament of the ankle joint. In the upper third of the leg, it lies between the tibialis anterior and the extensor digitorum longus, and in the middle third, between the tibialis anterior and extensor hallucis longus. At the ankle the artery is crossed from lateral to medial by the tendon of the extensor hallucis longus, lying between this latter tendon and the first tendon of the extensor digitorum longus. The vessel is covered in the upper two-thirds of the leg by muscles that lie on both sides and by the deep fascia. In the distal third of the leg it is covered by the skin and fascia, and by the extensor retinaculum.

The anterior tibial artery is accompanied by a pair of venae comitantes which course along the sides of the artery. The deep peroneal nerve, descending obliquely around the lateral aspect of the neck of the fibula, enters the anterior compartment of the leg to lie on the lateral aspect of the anterior tibial artery. At about the middle of the leg, the nerve lies anterior to the artery, but in the lower leg it again is usually on the lateral aspect.

**VARIATIONS.** The anterior tibial artery may be small or entirely absent, its place being taken by perforating branches from the posterior tibial, or by the perforating branch of the peroneal artery. Occasionally, the artery deviates toward the fibular side of the leg, regaining its usual position anterior to the ankle. More rarely, the vessel becomes superficial as high as the middle of the leg, being covered only by skin and fascia beyond that point.

### **Branches of the Anterior Tibial Artery**

The anterior tibial artery supplies vessels to the anastomosis around the knee joint, to the muscles in the anterior compartment of the leg, and to the anastomosis around the ankle joint, becoming at that point the **dorsalis pedis artery**. Its branches are:

- Posterior tibial recurrent
- Anterior tibial recurrent
- Muscular
- Anterior medial malleolar
- Anterior lateral malleolar

**Fig. 8-79.** Anterior tibial and dorsalis pedis arteries. Right leg.

### POSTERIOR TIBIAL RECURRENT ARTERY

The posterior tibial artery is an inconstant branch, but when present, it arises from the anterior tibial artery *before* that vessel achieves the anterior aspect of the leg. It ascends anterior to the popliteus muscle, which it supplies, and it anastomoses with the inferior genicular branches of the popliteal artery, sending a twig to the tibiofibular joint.

### ANTERIOR TIBIAL RECURRENT ARTERY

The anterior tibial recurrent artery arises from the anterior tibial immediately *after* that vessel has reached the anterior aspect of the leg (Figs. 8-78 to 8-80). It ascends in the tibialis anterior muscle, and ramifies on the front and sides of the knee joint, assisting in the formation of the arterial plexus. It anastomoses with the inferior genicular branches of the popliteal artery and with the circumflex fibular artery.

### MUSCULAR BRANCHES

Numerous muscular branches arise from the anterior tibial artery. They are distributed to the muscles that lie on both sides of the vessel. Some branches pierce the deep fascia to supply the skin, while others pass deeply through the interosseous membrane to anastomose with branches of the posterior tibial and peroneal arteries.

### ANTERIOR MEDIAL MALLEOLAR ARTERY

The anterior medial malleolar artery arises about 5 cm above the ankle joint, but it may arise lower down, even from the dorsalis pedis artery (Fig. 8-79). It passes behind the tendons of the extensor hallucis longus and tibialis anterior, to the medial aspect of the ankle. Its branches ramify over the medial malleolus and contribute to a network of vessels, anastomosing with branches from the posterior tibial and medial plantar arteries.

### ANTERIOR LATERAL MALLEOLAR ARTERY

The anterior lateral malleolar artery is generally larger than the anterior medial vessel (Fig. 8-80). It usually arises from the

anterior tibial artery distal to the lateral malleolus and may even arise from the dorsalis pedis artery. It passes deep to the tendons of the extensor digitorum longus and peroneus tertius and supplies the lateral aspect of the ankle. It anastomoses with the perforating branch of the peroneal artery and with ascending twigs from the lateral tarsal artery.

#### ANASTOMOSIS AROUND THE ANKLE JOINT.

The arteries around the ankle joint anastomose freely with one another to form networks below the corresponding malleoli. The **medial malleolar network** is formed by the anterior medial malleolar branch of the anterior tibial, the medial tarsal branches of the dorsalis pedis, the posterior medial malleolar and medial calcaneal branches of the posterior tibial, and branches from the medial plantar artery. The **lateral malleolar network** is formed by the anterior lateral malleolar branch of the anterior tibial, the lateral tarsal branch of the dorsalis pedis, the perforating and the lateral calcaneal branches of the peroneal, and twigs from the lateral plantar artery (Fig. 8-80).

#### Dorsalis Pedis Artery

The dorsalis pedis artery is the continuation of the anterior tibial artery beyond the ankle joint (Figs. 8-79; 8-80). It passes distally along the tibial side of the dorsum of the foot to the proximal part of the first intermetatarsal space. At this site the vessel divides into two terminal branches. These are the **first dorsal metatarsal artery**, which courses between the first and second toes, and the **deep plantar artery**, which penetrates between the two heads of the first dorsal interosseous muscle to enter the sole of the foot, helping to complete the plantar arch.

**RELATIONS OF THE DORSALIS PEDIS ARTERY.** The dorsalis pedis artery rests upon the anterior aspect of the articular capsule of the ankle joint. It continues distally in front of the talus, navicular, and intermediate cuneiform bones, and the ligaments interconnecting them. The artery is covered by the skin, fascia, and the inferior extensor retinaculum, and it is crossed near its termination by the first tendon of the extensor digitorum brevis. On its tibial or *medial aspect* is the tendon of the extensor hallucis longus. On its fibular or *lateral aspect* are the first tendon of the extensor digitorum longus and the termination of the deep peroneal nerve. The dorsalis pedis artery is usually accompanied by two veins.

**VARIATIONS.** The dorsalis pedis artery may be

larger than usual to compensate for a deficient lateral plantar artery. Its terminal branches to the toes may be absent, the toes then being supplied by the medial plantar, or its place may be taken by a large perforating branch of the peroneal artery (3%). In its descending course, the dorsalis pedis artery may lie lateral to the line between the middle of the ankle and the first interosseous space. In 12% of bodies, the dorsalis pedis is so small that it is essentially absent. The arcuate branch of the dorsalis pedis artery is a vessel of significant size in only 54% of feet studied (Huber, 1941).

#### Branches of the Dorsalis Pedis Artery

The dorsalis pedis artery supplies the dorsum of the foot with the following branches:

- Lateral tarsal
- Medial tarsal
- Arcuate
- First dorsal metatarsal
- Deep plantar

#### LATERAL TARSAL ARTERY

The lateral tarsal artery arises most frequently from the dorsalis pedis as that vessel crosses the head of the talus (Figs. 8-79; 8-80). It passes laterally in an arched course, lying upon the tarsal bones and covered by the extensor digitorum brevis muscle. The lateral tarsal artery supplies this muscle and the articulations of the tarsus. It anastomoses with branches of the arcuate, anterior lateral malleolar, and lateral plantar arteries, and with the perforating branch of the peroneal artery.

#### MEDIAL TARSAL ARTERIES

Two or three small medial tarsal arteries ramify on the medial border of the foot and join the medial malleolar network (Fig. 8-80).

#### ARCULATE ARTERY

The arcuate artery arises from the dorsalis pedis artery on the dorsum of the foot, between the medial cuneiform and the base of the second metatarsal bone (Fig. 8-79). It passes laterally over the bases of the second, third, and fourth metatarsal bones, deep to the tendons of the extensor digitorum brevis, its direction being influenced by its point of origin. It anastomoses with the lateral tarsal and lateral plantar arteries. The arcuate ar-

**FIG. 8-80.** The right anterior tibial and dorsalis pedis arteries and their branches. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 1975.)

tery gives off the **second, third, and fourth dorsal metatarsal arteries** (Fig. 8-80). These vessels course distally upon the corresponding dorsal interosseous muscles, and in the clefts between the toes, each divides into two **dorsal digital arteries** for the adjoining toes (Fig. 8-80). At the proximal parts of the interosseous spaces, the dorsal metatarsal arteries receive perforating branches from the plantar arch, and at the distal parts of the spaces they are joined by other perforating branches from the plantar metatarsal arteries. The fourth dorsal metatarsal artery gives off a branch that supplies the lateral aspect of the fifth toe.

### FIRST DORSAL METATARSAL ARTERY

The first dorsal metatarsal artery courses distally on the first dorsal interosseous muscle and, at the cleft between the first and second toes, divides into two branches. One of these passes deep to the tendon of the extensor hallucis longus and is distributed to the medial border of the great toe; the other bifurcates to supply the adjoining sides of the great and second toes.

### DEEP PLANTAR ARTERY

The deep plantar artery penetrates into the sole of the foot between the two heads of the first dorsal interosseous muscle and unites with the termination of the lateral plantar artery, thereby completing the **plantar arch** (Figs. 8-79; 8-80). On the plantar aspect of the foot, it sends a branch along the medial side of the great toe, continuing distally along the first interosseous space as the **first plantar metatarsal artery** (Figs. 8-82; 8-83). This latter vessel bifurcates and thereby supplies the adjacent sides of the first and second toes.

### Posterior Tibial Artery

The posterior tibial artery begins at the lower border of the popliteus muscle, opposite the interval between the tibia and fibula (Figs. 8-77; 8-81). It is larger than the anterior tibial artery, and it descends obliquely downward and medially in the posterior compartment of the leg between the superficial and deep muscle layers. As it approaches the tibial side of the leg, lying behind the tibia in the lower part of its course, the vessel is situated midway between the medial malleolus and the medial process of the calcaneal tuberosity. Under cover of the origin of the abductor hallucis it divides into the **medial and lateral plantar arteries** (Figs. 8-82; 8-83).

**RELATIONS OF THE POSTERIOR TIBIAL ARTERY.** The posterior tibial artery lies successively upon the tibialis posterior, the flexor digitorum longus, the tibia, and the posterior part of the ankle joint. It is covered in the upper part of the leg by the deep transverse fascia that separates it from the gastrocnemius and soleus, and at its entrance into the foot, it is covered by the abductor hallucis muscle. In the distal third of the leg, the artery is more superficial,

being covered only by skin and fascia, and it courses parallel but anterior to the medial border of the tendo calcaneus. The posterior tibial artery is accompanied by two veins and by the tibial nerve. The latter structure at first lies medial to the artery, but soon crosses the vessel posteriorly, and throughout most of its course lies lateral to the artery.

Deep to the flexor retinaculum behind the medial malleolus, the tendons, blood vessels, and nerve are arranged from medial to lateral in the following order: the tendons of the tibialis posterior and flexor digitorum longus, the posterior tibial artery with a vein on each side, the tibial nerve, and, 1.25 cm nearer the heel, the tendon of the flexor hallucis longus.

**VARIATION.** The posterior tibial artery quite frequently is smaller than usual or even absent. In these cases its field is supplied by a large peroneal artery, which either joins the small posterior tibial artery or continues alone to the sole of the foot.

#### Branches of the Posterior Tibial Artery

From the posterior tibial artery arise the following branches:

- Circumflex fibular
- Peroneal
- Nutrient (tibial)
- Muscular
- Medial malleolar
- Communicating
- Medial calcaneal
- Medial plantar
- Lateral plantar

#### CIRCUMFLEX FIBULAR ARTERY

The circumflex fibular artery usually arises from the upper end of the posterior tibial artery, but may arise from the popliteal artery or even from the anterior tibial artery. It pierces the fibular head of the soleus muscle, winds around the neck of the fibula, and supplies the soleus along with the peroneal muscles arising from the upper fibula. It participates in the anastomosis around the lateral aspect of the knee joint (Fig. 8-78).

#### PERONEAL ARTERY

The peroneal artery is deeply located on the fibular side of the back of the leg. It arises from the posterior tibial artery about 2.5 cm distal to the lower border of the popliteus muscle (Figs. 8-77; 8-81). It passes

obliquely toward the fibula and then descends along the medial aspect of that bone, contained in a fibrous canal between the tibialis posterior and the flexor hallucis longus, or in the substance of the latter muscle. The peroneal artery then runs behind the tibiofibular syndesmosis, ending in lateral calcaneal branches which ramify over the lateral and posterior surfaces of the calcaneus. In the proximal part of the leg, the peroneal artery is covered by the soleus muscle and the deep transverse fascia. More distally, it lies deep to the flexor hallucis longus muscle.

**VARIATIONS.** The peroneal artery may arise from the posterior tibial artery higher than normal, or even from the popliteal artery. In contrast, it may arise as far as 7 or 8 cm below the popliteus muscle. If the vessel is larger than normal, it either reinforces the posterior tibial by joining it, or when it is very large, altogether takes the place of the posterior tibial in the distal part of the leg and foot. In the rarer instances, when the peroneal artery is smaller than normal, another branch from the posterior tibial helps to supply its muscular field, and a branch from the anterior tibial compensates for the diminished perforating artery. In 3% of specimens, the perforating branch of the peroneal artery is considerably enlarged and it takes the place of the dorsalis pedis artery.

#### Branches of the Peroneal Artery

The peroneal artery supplies vessels to structures in the lateral aspect of the leg. The branches are:

- Muscular
- Nutrient (fibular)
- Perforating
- Communicating
- Lateral malleolar
- Lateral calcaneal

**MUSCULAR BRANCHES.** Muscular branches of the peroneal artery go to the soleus, tibialis posterior, flexor hallucis longus, and peroneal muscles.

**NUTRIENT ARTERY.** The nutrient artery from the peroneal is directed downward and enters the nutrient canal of the fibula.

**PERFORATING BRANCH.** The perforating branch of the peroneal artery pierces the interosseous membrane about 5 cm above the lateral malleolus to reach the anterior part of

**FIG. 8-81.** The right posterior tibial artery and its branches. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 1975.)

the leg, where it anastomoses with the anterior lateral malleolar artery (Figs. 8-77; 8-79; 8-80). It then descends anterior to the tibiofibular syndesmosis, gives branches to the tarsus, and anastomoses with the lateral tarsal artery.

**COMMUNICATING BRANCH.** A communicating branch arises from the peroneal artery about 5 cm from its distal end (Fig. 8-77). It courses transversely across the leg just posterior to the interosseous membrane to join the communicating branch of the posterior tibial.

**LATERAL MALLEOLAR BRANCHES.** Several

small lateral malleolar branches arise from the peroneal artery; they wind around the lateral malleolus and join the lateral malleolar network (Fig. 8-77).

**LATERAL CALCANEAL BRANCHES.** Lateral calcaneal branches are the terminal vessels of the peroneal artery (Figs. 8-77; 8-81). They pass to the lateral aspect of the heel and communicate with the anterior lateral malleolar branch of the anterior tibial and with the lateral malleolar branches of the peroneal artery. On the back of the heel, they anastomose with the medial calcaneal branches of the posterior tibial.

**NUTRIENT ARTERY**

The nutrient artery of the tibia arises from the posterior tibial artery near its origin. It pierces the tibialis posterior muscle to which it gives several muscular branches, and then it descends obliquely to enter the nutrient canal of the tibia, located just below the soleal line. Within the bone, the nutrient artery divides into an **ascending branch**, which supplies the superior end of the tibia, and a **descending branch**, which supplies the body and inferior end of the bone. It is the largest nutrient artery to a bone in the body and is accompanied to the bone by a branch of the nerve to the popliteus muscle.

**MUSCULAR BRANCHES**

Muscular branches of the posterior tibial artery are distributed to the soleus and to the deep muscles along the back of the leg.

**MEDIAL MALLEOLAR ARTERY**

The medial malleolar artery is a small branch of the posterior tibial artery which winds around the tibial malleolus and joins in the medial malleolar network (Figs. 8-77; 8-81).

**COMMUNICATING BRANCH**

A communicating branch arises from the posterior tibial artery about 5 cm above the medial malleolus (Fig. 8-77). It courses transversely across the posterior aspect of the tibia and the interosseous membrane. Deep to the flexor hallucis longus muscle, it joins the communicating branch of the peroneal artery.

**MEDIAL CALCANEAL ARTERIES**

The medial calcaneal arteries are several large vessels that arise from the posterior tibial artery just before it divides into the medial and lateral plantar arteries (Figs. 8-77; 8-80). Frequently, however, they branch from the lateral plantar rather than the posterior tibial. They pierce the flexor retinaculum and are distributed to the fat and skin behind the tendo calcaneus and about the heel, also helping to supply the muscles on the tibial side of the sole of the foot. The medial calcaneal arteries anasto-

mose with the medial malleolar branches of the posterior tibial, and on the back of the heel, with the lateral calcaneal branches of the peroneal artery (Fig. 8-81).

**MEDIAL PLANTAR ARTERY**

The medial plantar artery is the smaller of the two terminal branches of the posterior tibial artery (Figs. 8-82; 8-83). It passes distally along the medial aspect of the foot and is at first situated deep to the abductor hallucis, and then between it and the flexor digitorum brevis, both of which it supplies. At the base of the first metatarsal bone, and much diminished in size, it passes along the medial border of the first toe, anastomosing with a branch of the first plantar metatarsal artery. Small superficial digital branches accompany the digital branches of the medial plantar nerve, and these join the plantar metatarsal arteries of the first three spaces (Fig. 8-82).

**LATERAL PLANTAR ARTERY**

The lateral plantar artery is much larger than the medial plantar. Initially, it passes obliquely lateralward to the base of the fifth metatarsal bone, and then it curves medially to the interval between the bases of the first and second metatarsal bones (Figs. 8-82; 8-83). There it unites with the deep plantar branch of the dorsalis pedis artery, which completes the formation of the **plantar arch** (Fig. 8-83). As the lateral plantar artery passes laterally, it is first placed between the calcaneus and abductor hallucis muscle, and then between the flexor digitorum brevis and quadratus plantae muscles. As it runs distally along the base of the little toe, it lies more superficially between the flexor digitorum brevis and abductor digiti minimi, and is covered only by the plantar aponeurosis, superficial fascia, and skin.

**PLANTAR ARCH.** The remaining portion of the lateral plantar artery is the more deeply situated plantar arch (Fig. 8-83). Extending from the base of the fifth metatarsal bone, the plantar arch penetrates through the layers of the sole of the foot to course medially, beneath the adductor hallucis. It crosses the plantar surface of the bases of the fourth, third, and second metatarsal bones and the corresponding interosseous muscles. At the

**FIG. 8-82.** The more superficial branches of the plantar arteries as seen after removal of the plantar aponeurosis. Right foot. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, 1975.)

proximal part of the first interosseous space, the plantar arch is completed by its junction with the deep plantar branch of the dorsalis pedis artery. Besides distributing numerous branches to the muscles, integument, and fasciae in the sole, the plantar arch gives rise to three perforating and four plantar metatarsal arteries.

The three **perforating branches** of the plantar arch penetrate through the proximal parts of the second, third, and fourth interosseous spaces, between the heads of the dorsal interosseous muscles, to anastomose with the dorsal metatarsal arteries.

The four **plantar metatarsal arteries** course distally between the metatarsal bones and lie in contact with the interosseous mus-

cle (Figs. 8-82; 8-83). Each vessel divides into two **plantar digital arteries**, which supply the adjacent sides of the toes. Near their points of division each plantar metatarsal artery gives off an **anterior perforating branch** to join the corresponding dorsal metatarsal artery.

The **first plantar metatarsal artery** springs from the junction between the plantar arch and the deep plantar branch of the dorsalis pedis artery (Figs. 8-82; 8-83). It sends a digital branch to the medial aspect of the large toe. The digital branch for the lateral aspect of the little toe arises from the lateral plantar artery near the base of the fifth metatarsal bone, just as the latter vessel curves medially to become the plantar arch.

**FIG. 8-83.** The deep arteries on the plantar aspect of the right foot. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 1975.)

# 9

## The Veins

The venous system conveys blood from the capillaries to the heart. There are two distinct sets of veins, the **pulmonary** and the **systemic**. These serve two different vascular circuits: the **pulmonary veins** return blood to the heart from the lungs, and the **systemic veins** return blood to the heart from the rest of the body.

The pulmonary veins return oxygenated blood from the capillaries of the lungs to the left atrium of the heart. The blood then continues through the left ventricle and aorta to supply all the body organs.

The systemic veins belong to the larger systemic circulation and convey deoxygenated blood from all the organs except the lungs to the right atrium of the heart. Blood from all the systemic veins except those of the heart eventually flows through the superior and inferior venae cavae to the right atrium. The **coronary veins** flow into the coronary sinus, which then also opens into the right atrium.

The **portal vein** is interposed between certain abdominal viscera and the liver. Its special feature is that it both begins and ends in capillaries. The portal vein receives venous blood from the capillaries of the digestive tube, spleen, and pancreas and delivers it to the venous capillary-like sinusoids of the liver. The blood then makes its way into the general systemic venous system through the tributaries of the hepatic veins, which flow into the inferior vena cava.

The veins are the most variable part of the cardiovascular system. Variations in venous patterns are more frequent in vessels that drain the more superficial parts of the body than in the deeper coursing veins which often accompany the arteries. At times veins exist in pairs, one lying on each side of an artery. These are called **venae comitantes** and are often seen in the medium-sized vessels of the arm, forearm, and leg (brachial, radial, ulnar, and tibial). The larger arteries (axillary, femoral, and popliteal) usually have only one accompanying vein. In certain organs and body regions, however, the deep veins do not accompany arteries; this is true of the venous sinuses in the skull and vertebral canal, the hepatic veins, and the large veins draining blood from the long bones.

### Development of the Veins

The development of veins actually commences when minute plexuses of vessels receive blood from the earliest developing capillaries. These plexuses give rise to tributaries that finally unite to form trunks. Passing toward the heart, the trunks increase in size as they receive other tributaries or as they join other veins.

The further development of the venous system in the human embryo will be considered by dividing the veins into two groups: the **parietal veins**, which drain the body cavity, extremities, and head and form the large inferior and superior venae cavae, and the **visceral veins**, which drain the yolk sac and placenta and join to form the sinus venosus.

#### PARIETAL VEINS

The parietal veins, which drain most of the developing embryonic structures, are initially represented by four large vessels: the two **anterior cardinal** (or precardinal) **veins** and the two **posterior cardinal** (or postcardinal) **veins** (Figs. 9-1, A; 9-3). The two anterior cardinal veins, one lying on each side of the embryo, drain the more cranial venous tributaries, returning blood from the head, and soon become the primitive jugular veins. The two posterior cardinal veins, also one on each side, drain the caudal venous tributaries of the embryo, returning

**FIG. 9-1.** Schematic diagrams showing certain stages in the development of the inferior vena cava between the fourth and eighth prenatal weeks and at term, based on the work of McClure and Butler (1925). Anterior and posterior cardinal veins are shown in solid black, supracardinal veins are hatched horizontally. † (in B) = vessels from the upper part of the right subcardinal vein and liver that commence forming the hepatic segment of the inferior vena cava; Ob. (in E) = oblique vein of the left atrium; \* (in F) = left superior intercostal vein. (From Patten, B. M., *Human Embryology*, 3rd ed., McGraw-Hill, New York, 1968.)

blood from the lower body wall, the pelvis, the mesonephroi (Wolffian<sup>1</sup> bodies), and the lower limb buds. The anterior and posterior cardinal veins on each side join to form a symmetrically arranged longitudinally oriented cardinal system (Fig. 9-1, A). Two short transverse veins, the **common cardinal veins** (ducts of Cuvier<sup>2</sup>), interconnect the anterior and posterior cardinal veins of each side to the corresponding horns of the sinus venosus (Figs. 9-1, B; 9-4, A).

To this relatively simple pattern are added, during the fifth week of development, the **subcardinal veins**. These veins develop parallel and ventral to the posterior cardinal veins in the ventromedial part of the mesonephric ridges and gradually take over the drainage of the mesonephroi from the posterior cardinal veins (Fig. 9-1, B). During the seventh week are added the **supracardinal veins**, which form dorsomedial to the posterior cardinal veins (Fig. 9-1, D).

This primitive double (right and left) plan of veins then is converted to the single caval system, in which blood is returned to the heart through the inferior and superior venae cavae.

**INFERIOR VENA CAVA.** The principal changes that occur to form the vena caval systems in the embryo culminate in the alteration of the bilaterally symmetrical venous plan, initiated by the formation of the anterior and posterior cardinal veins along with the subcardinal veins, into large unpaired vessels found on the right side of the body (the superior and inferior venae cavae). The peripheral channels in the head and limbs that flow into these centrally unpaired veins still retain much of their symmetry.

The inferior vena cava, which drains blood from the lower trunk, pelvis, and lower limbs, gradually develops by replacing the various cardinal veins or by utilizing portions of them. Initially, the subcardinal veins begin to replace partially the posterior cardinal veins as the drainage channels of the mesonephroi. These channels soon form many cross connections with the posterior cardinal veins on each side (Fig. 9-1, A). As

the mesonephroi grow, they approximate medially, and consequently the subcardinal veins of the two sides become nearly adjacent. By five and one-half weeks, the two subcardinal veins establish an interconnection called the **intersubcardinal anastomosis** (Fig. 9-1, B), which then enlarges to form the **subcardinal sinus**. Soon blood begins to flow medially into this sinus from the many small vessels that had interconnected the posterior cardinal and the subcardinal veins. This results in a disappearance of the more caudal parts of the posterior cardinal veins (Fig. 9-1, C).

As the subcardinal sinus forms, the veins of the superior pole of the right mesonephros, which lie close to the developing liver, anastomose with some of the vessels flowing through the liver. This anastomosis occurs within a fold of mesentery called the **caval fold** (or mesentery), into which have grown capillaries from the liver above and some capillaries from the right subcardinal veins below (Fig. 9-1, B and C). Soon this anastomosis enlarges within the substance of the liver and becomes a principal venous channel. It achieves the surface of the liver as the **hepatic part of the inferior vena cava**. The right omphalomesenteric vein enlarges to form the **suprahepatic portion of the inferior vena cava**, which is the segment between the liver and the right atrium. The portion of the inferior vena cava arising above the kidneys, which can be called the **prerenal part**, consists of the renal segment (subcardinal sinus), the hepatic segment, and the suprahepatic segment.

Below the level of the kidneys, the two **supracardinal veins** participate in the formation of the **postrenal part** of the inferior vena cava (Fig. 9-1, C and D). These veins arise during the seventh week, and they are seen initially as a periganglionic plexus of veins associated with the developing sympathetic ganglionic chain. The supracardinal veins develop as a pair of longitudinally oriented vessels that drain the posterior body wall dorsal to the posterior cardinal veins. Near the level of the middle part of the developing mesonephros, the supracardinal veins merge with the subcardinal sinus.

Above the subcardinal sinus, together with the persisting proximal part of the right postcardinal vein, the supracardinal vein forms the **azygos system of veins** (Fig. 9-1, E

<sup>1</sup>Kasper F. Wolff (1733-1794): A German embryologist and physiologist, who worked in St. Petersburg, Russia.

<sup>2</sup>Georges L. Cuvier (1769-1832): A French zoologist and natural historian (Paris).

and F). The proximal part of the left supra-cardinal vein, together with some of the upper part of the left postcardinal vein, forms the **hemiazygos**, **accessory hemiazygos**, and the **left superior intercostal vein**.

Below the subcardinal sinus, blood from the lower limbs is collected by the right and left iliac veins, which in the earlier stages of development open into the corresponding right and left posterior cardinal veins. Later a transverse **iliac anastomosis**, which at this stage connects the right and left iliac vein, eventually develops into the **left common iliac vein** (Fig. 9-1, C to F). Blood returning from the lower extremities increasingly is shunted from the lower end of the right postcardinal vein to the right supracardinal vein. As the postcardinal vein gradually disappears, the lower part of the right supra-cardinal vein enlarges and forms the **post-renal part of the inferior vena cava** (Fig. 9-1, E and F).

Above the subcardinal sinus, the left posterior cardinal-subcardinal vein disappears, except the part immediately above the renal vein, which is retained as the **left suprarenal vein**. The fate of the left posterior cardinal-subcardinal system also accounts for the fact that the left gonadal vein (testicular or ovarian) opens into the left renal vein, while the vein on the right side drains into the post-renal segment of the inferior vena cava (Fig. 9-1, E and F).

**SUPERIOR VENA CAVA.** The superior vena cava develops at the junction of the two brachiocephalic veins, which in turn receive blood from the head by way of the internal and external jugular veins and from the

upper limb by means of the subclavian vein. The primitive **internal jugular veins**, which drain the cranial end of the embryo on each side, initially are simply the anterior cardinal veins, whereas the **external jugular veins** develop in the region of the mandible by the junction of a number of smaller, more superficial vessels (Fig. 9-1, B to D).

At four weeks the lower portion of the anterior cardinal vein joins the posterior cardinal vein to form the common cardinal vein (Figs. 9-1, A; 9-2, A). Because the heart as well as the common cardinal veins lie far to the cranial end of the developing embryo at the time that the upper limb buds appear, the initial veins that drain the upper limb buds flow into the posterior cardinal veins (Fig. 9-1, B). As development continues, the heart descends relative to the upper limb buds, and soon the limb bud veins (axillary) begin to drain into the more caudal part of the anterior cardinal vein (internal jugular). When this occurs (sixth to seventh weeks), the primitive pattern of two brachiocephalic veins (right and left superior venae cavae) is formed (Figs. 9-1, C; 9-2, B). About this same time, an anastomosis forms between the two anterior cardinal veins, which results in the formation of a transverse connecting vein in front of the trachea as a confluence of thymic and thyroid veins. This anastomosis becomes the **left brachiocephalic vein**, and it allows blood returning from the cranial left side of the embryo to be shunted to the right side of the heart, where it must enter the right atrium (Figs. 9-1, D; 9-2, B). The junction of the two brachiocephalic veins eventually forms the superior

**FIG. 9-2.** Diagrams showing the transformation of the cardinal veins into the superior vena cava in human embryos at six weeks (A), eight weeks (B), and in the adult (C). H.I. = left superior intercostal vein (highest intercostal); O.V. = oblique vein of the left atrium; S = left subclavian vein. (From Arey, L. B., *Developmental Anatomy*, 7th ed., W. B. Saunders Co., Philadelphia, 1974.)

vena cava (Fig. 9-1, D to F). The remainder of the left anterior cardinal vein, below the left brachiocephalic, becomes much smaller, but it contributes to the formation of the **left superior intercostal vein**, in conjunction with the small remaining cranial end of the left posterior cardinal vein. The right anterior cardinal vein between the azygos vein and the union with the left brachiocephalic vein becomes the upper part of the adult **superior vena cava**. The lower part of the superior cava, that is, the part between the azygos vein and the heart, is formed by the original right common cardinal vein (duct of Cuvier). The left anterior cardinal vein, caudal to the transverse left brachiocephalic vein and left superior intercostal vein, and the left common cardinal vein regress. The upper part becomes the **vestigial fold of Marshall**<sup>1</sup> (Figs. 9-1, E and F; 9-2), and the proximal part of the left common cardinal vein becomes the **oblique vein of the left atrium** (of Marshall). The oblique vein of the left atrium drains across the dorsal surface of the left atrium to open into the **coronary**

**sinus**, which represents the persistent left horn of the sinus venosus. Both the right and left superior venae cavae are present in some animals, and occasionally are found as anomalies in adult human beings.

### VISCERAL VEINS

The **visceral veins** are the two **vitelline** or **omphalomesenteric veins** which bring blood to the embryo from the yolk sac, and the two **umbilical veins** which return oxygenated fetal blood to the embryo from the placenta. These four veins open into the **sinus venosus**.

**VITELLINE VEINS.** The paired vitelline veins follow the stalk of the yolk sac, and thereby enter the body of the embryo. They course cranially, at first ventral to and then on either side of the developing foregut, each on its way to its respective horn of the sinus venosus. The vitelline veins unite on the ventral aspect of the intestinal canal, and more cranially, they are connected to each other by two anastomotic branches, one on the dorsal and the other on the ventral aspect of the duodenal portion of the intestine,

**FIG. 9-3.** Semischematic diagram showing the basic vascular plan of the human embryo at the end of first month. For the sake of simplicity, the paired vessels are shown only on the side toward observer. (From Patten, B. M., *Human Embryology*, 3rd ed., McGraw-Hill, New York, 1968.)

**Fig. 9-4.** Diagrams showing steps in the development of the hepatic-portal circulation from the omphalomesenteric veins, and the changes by which blood returning in the umbilical veins from the placenta is rerouted through the liver. A, fourth week; B, fifth week; C, sixth week; D, seventh week and older. The asterisk in C indicates the hepatic part of the inferior vena cava. (From Patten, B. M., *Human Embryology*, 3rd ed., McGraw-Hill, New York, 1968.)

which is thus encircled by two venous rings (Fig. 9-4, B). Into the middle or dorsal anastomosis opens the superior mesenteric vein, which arises in the dorsal mesentery of the intestine. Within the septum transversum, the portions of the veins above the upper ring are interrupted by the developing liver and are broken up by it into a plexus of small capillary-like vessels termed **sinusoids**. The vessels conveying blood to this plexus become the tributaries of the **portal**

**vein**, while the vessels draining the plexus from the liver into the sinus venosus form the future **hepatic veins** (Figs. 9-4, C and D; 9-5). Ultimately the left vitelline (hepatic) veins no longer communicate directly with the sinus venosus, but open into the developing right hepatic veins. The persistent part of the upper venous ring, above the opening of the superior mesenteric vein, forms the trunk of the portal vein.

**UMBILICAL VEINS.** The two umbilical veins

**FIG. 9-5.** Human embryo with heart and anterior body wall removed to show the sinus venosus and its tributaries. (After His.)

return oxygenated blood to the embryo from the placenta. They form a single trunk in the body stalk, but remain separate within the embryo and pass forward to the sinus venosus in the side walls of the embryonic body (Fig. 9-4, B). Like the vitelline veins, their direct connection with the sinus venosus becomes interrupted by the developing liver, and thus at this stage (6 mm, fifth week), all the blood from the yolk sac and placenta passes through the substance of the liver before reaching the heart. During the sixth week, the two umbilical veins commence to fuse in the umbilical cord, and the left umbilical channel becomes the principal course for the returning blood (Figs. 9-4, C; 9-5). In the embryo the right umbilical and right vitelline veins shrivel and disappear, while the left umbilical vein enlarges and opens into the upper venous ring of the vitelline veins. When the yolk sac atrophies, the left vitelline vein also undergoes atrophy and disappears (Fig. 9-5). Finally, a direct branch is established between this ring and the right

hepatic vein. This branch enlarges rapidly into a wide channel named the **ductus venosus** (Fig. 9-4, C and D). Through the ductus venosus most of the blood is returned from the placenta and carried directly to the heart without passing through the liver. The left umbilical vein and the ductus venosus undergo atrophy and obliteration after birth, and form respectively the **ligamentum teres** and **ligamentum venosum** of the liver.

## The Pulmonary Veins

The **pulmonary veins**, two from each lung, return oxygenated blood to the left atrium of the heart (Fig. 9-6). The capillary networks in the walls of the air sacs join together to form one vessel for each lobule. These vessels unite successively to form a single trunk for each lobe, three for the right and two for the left lung. The vein from the middle lobe of the right lung usually unites with that from the superior lobe so that ultimately two

**Fig. 9-6.** Diagrammatic representation of the branches of the superior and inferior pulmonary veins on each side of the body. (Redrawn after *Nomina Anatomica*, 1968, Excerpta Medica Foundation.)

trunks are formed from each lung. Near the heart, the four pulmonary veins perforate the fibrous layer of the pericardium and open separately into the superior part of the left atrium (Fig. 9-7). The three veins from the right lung may remain separate, and at times the two left veins join and enter the heart by a common opening.

At the roots of the lungs, the superior pulmonary veins lie anterior and a little inferior to the pulmonary arteries. The inferior veins are situated in the most caudal part of the hilum on a plane posterior to the superior veins. The pulmonary veins are about 1.5 cm in length, and on the right side they pass behind the right atrium and superior vena cava to reach the left atrium. The left pulmonary veins course anterior to the descending thoracic aorta on their way to the heart.

Within the lung the ramifications of the veins do not always accompany the bronchi and arteries in the central regions of the bronchopulmonary segments. More superficially near the pleura, they are found between bronchopulmonary segments, or more deeply, they are found intrasegmentally. The

branchings of both the larger and the smaller tributaries are quite variable. A list of the bronchopulmonary segments is found in Chapter 15.

#### RIGHT SUPERIOR PULMONARY VEIN

The right superior pulmonary vein has three tributaries for the superior lobe and one for the middle lobe (Fig. 9-6).

**APICAL SEGMENTAL VEIN.** The apical segmental vein lies near the mediastinal pleura. It has an *intrasegmental* tributary draining the apex and an *infrasegmental* tributary separating the apical from the anterior segments.

**POSTERIOR SEGMENTAL VEIN.** The posterior segmental vein is the largest vein of the superior lobe and has both *intralobar* and *infralobar* parts. The *intralobar* part has an apical, a posterior, and an intersegmental tributary, which is a prominent vein of the posterior surface. The *infralobar* part lies near the pleura between the superior and middle lobes.

**ANTERIOR SEGMENTAL VEIN.** The anterior segmental vein has two tributaries, *intrasegmental* and *infrasegmental*. These accompany the two branches of the anterior segmental bronchus of the right superior lobe.

**RIGHT MIDDLE LOBE VEIN.** The right middle lobe vein is usually a single tributary of the right superior pulmonary vein, but its two segmental veins may remain separate. The *lateral segmental vein* splits into a tributary for the lateral segment and a tributary separating the segments. The *medial segmental vein* lies near the mediastinal surface and has two tributaries, one subpleural and one *intrasegmental*.

#### RIGHT INFERIOR PULMONARY VEIN

The right inferior pulmonary vein occupies the most inferior part of the hilum of the right lung, and has two main tributaries, a superior (or apical) segmental vein and a common basal vein (Fig. 9-6).

**SUPERIOR (OR APICAL) SEGMENTAL VEIN.** The superior segmental vein begins near the medial side of the middle lobe bronchus and is formed by two or three tributaries with *intrasegmental* and *infrasegmental* tributaries.

**COMMON BASAL VEIN.** The common basal vein is a large short trunk that drains the four basal segments of the lower lobe of the right lung. It has two principal tributaries, a superior basal and an inferior basal. The **superior basal** tributary lies deep to the surface of the inferior lobe and drains both its anterior basal and lateral basal bronchopulmonary segments by *intrasegmental* and *infrasegmental* tributaries. The **inferior basal** tributary drains the posterior basal and lateral basal bronchopulmonary segments. The medial basal bronchopulmonary segment is drained by several tributaries that open into both the superior basal and inferior basal veins.

#### LEFT SUPERIOR PULMONARY VEIN

The left superior pulmonary vein drains blood from the two bronchopulmonary segments of the superior lobe, as well as from the two segments of the lingula of the superior lobe. It is formed by a confluence of the

apicoposterior segmental vein, the anterior segmental vein, and the lingular division vein. The latter vein is formed by the junction of the superior and inferior lingular veins (Fig. 9-6).

**APICOPOSTERIOR SEGMENTAL VEIN.** The apicoposterior segmental vein is formed by the junction of an *intrasegmental* tributary and an *infrasegmental* tributary.

**ANTERIOR SEGMENTAL VEIN.** The anterior segmental vein drains the anterior segment of the left superior lobe, and is formed by *intrasegmental* and *infrasegmental* tributaries.

**LINGULAR DIVISION VEIN.** The lingular division vein drains the superior lingular and inferior lingular segments. The superior lingular vein has posterior and anterior intersegmental tributaries. The tributaries of the inferior lingular vein are superior and inferior. The latter drains into the inferior pulmonary vein in some instances.

#### LEFT INFERIOR PULMONARY VEIN

The left inferior pulmonary vein receives a smaller apical superior segmental vein and a larger common basal segmental vein (Fig. 9-6).

**APICAL SUPERIOR SEGMENTAL VEIN.** The apical superior segmental vein lies on the medial side of the superior lobe bronchus and is itself formed by a central *intrasegmental* and two *intersegmental* tributaries, the latter separating the segment from its neighbors.

**COMMON BASAL VEIN.** The common basal vein receives the **superior basal vein**, which largely drains the anterior basal segment by *intrasegmental* and *infrasegmental* tributaries, and the **inferior basal vein**, which drains the posterior basal and lateral basal segments by *intrasegmental* and *infrasegmental* tributaries. The medial basal bronchopulmonary segment is drained by two venous channels, one *intrasegmental* and the other *intersegmental*; the latter separates the medial basal segment from the posterior basal segment. One or both of these veins drains into the common basal vein.

The *anterior basal vein*, which drains into the superior basal division of the common basal vein, has an *intrasegmental* and an *infrasegmental* tributary; the latter usually

lies deep to the pulmonary ligament and separates the medial basal from the lateral basal bronchopulmonary segments. The *lateral basal vein*, which drains into the inferior basal division of the common basal vein, is primarily an intersegmental vessel in the depth of the lobe between the lateral basal and posterior basal bronchi, but it also has an intrasegmental tributary. The *posterior basal vein*, which also drains into the inferior basal division of the common basal vein, is intrasegmental; it lies in the hollow between the branches of the posterior basal segmental bronchus and drains these regions by two tributaries.

## The Systemic Veins

The **veins** commence as minute plexuses that receive blood from the capillaries. The tributaries arising from these plexuses unite into trunks, and these, in their passage toward the heart, constantly increase in size as they receive tributaries or join other veins. The veins are larger in caliber and more numerous than the arteries, giving the venous system a larger capacity than that of the arterial system. The capacity of the pulmonary veins, however, only slightly exceeds that of the pulmonary arteries. The veins, when full, are cylindrical like the arteries, but their walls are thin and they collapse when empty. In the cadaver, they may be interrupted at intervals by nodular enlargements that indicate the existence of **valves** in their interior.

Veins anastomose freely, especially in certain regions of the body. These communications exist between large trunks as well as between smaller branches. Between the venous sinuses of the cranium, and between the veins of the neck, where obstruction would bring imminent danger to the cerebral venous system, large and frequent anastomoses are found. The same free communication exists between the veins throughout the entire extent of the vertebral canal, and between the veins composing the various venous plexuses in the abdomen and pelvis. Three types of venous channels can be identified according to their location in the body: superficial veins, deep veins, and venous sinuses.

**SUPERFICIAL VEINS.** The superficial veins

are found within the substance of the superficial fascia immediately beneath the skin. They drain the capillary networks near the surface of the body and return this blood to deeper veins by perforating the deep fascia. Some of the larger superficial veins include the facial vein, which drains the superficial structures of the face, the cephalic and basilic veins of the upper extremity, the thoracoepigastric vein of the anterior trunk, and the great and small saphenous veins of the lower extremity.

**DEEP VEINS.** The deep veins generally accompany the deeper coursing arteries and usually are enclosed in the same sheaths as the vessels. The larger arteries, such as the axillary, subclavian, popliteal, and femoral, usually have only one accompanying vein. In the case of the smaller arteries, such as the radial, ulnar, brachial, tibial, and peroneal, the veins exist generally in pairs, one lying on each side of the vessel, and are called **venae comites** or **venae comitantes**. In certain organs of the body, however, the deep veins do not accompany the arteries. Examples of these are the veins in the skull and vertebral canal, the hepatic veins in the liver, and the larger veins that return blood from the bones.

**VENOUS SINUSES.** Throughout the body are veins to which the term sinus has been given. At times a sinus is a vessel that does not have the same layers in its walls as other veins, but this definition cannot be applied consistently. Within the cranial cavity of the skull are found venous sinuses that consist of canals formed by a separation of the two layers of the dura mater. Their outer coat consists of fibrous tissue, their inner of an endothelial layer continuous with the lining of the veins. The coronary sinus is the vessel into which drain the veins of the heart. Small venous capillary channels in the liver are called venous sinusoids. The sinus venosus is a venous channel found in the embryonic heart.

The systemic veins may be arranged in four groups: (1) the cardiac veins or veins of the heart; (2) the superior vena cava and its tributaries, which include the veins of the head, neck, upper limbs, and thorax; (3) the inferior vena cava and its tributaries, which include the veins of the lower limbs, some veins of the abdomen, and the veins of the pelvis; and (4) the portal system of veins.

## Veins of the Heart

The veins of the heart, or the **cardiac veins**, with the exception of certain small vessels that open directly into the chambers, are tributaries of the coronary sinus.

### CORONARY SINUS

The coronary sinus is a wide venous channel, about 2.25 cm in length, situated in the posterior part of the coronary sulcus of the heart, and usually covered by muscular fibers from the left atrium (Fig. 9-7). It ends in the right atrium, between the opening of the inferior vena cava and the atrioventricular aperture; its orifice is guarded by a single semilunar valve, the **valve of the coronary sinus** (valve of Thebesius<sup>1</sup>). This valve does not appear to have any functional significance in the adult heart.

Most of the venous blood returning from heart tissue courses in veins that open into

the coronary sinus. These tributaries include the:

- Great cardiac vein
- Small cardiac vein
- Middle cardiac vein
- Posterior vein of the left ventricle
- Oblique vein of the left atrium

Each of these veins, except the last, is provided with a valve at its orifice.

**GREAT CARDIAC VEIN.** The great cardiac vein begins at the apex of the heart and ascends along the anterior interventricular sulcus to the base of the ventricles (Figs. 8-16; 8-18). It then curves to the left in the coronary sulcus, and reaching the back of the heart, opens into the left extremity of the coronary sinus (Fig. 9-7). It receives tributaries from the left atrium and from both ventricles. One of these, the **left marginal vein**, is of considerable size and ascends along the left margin of the heart (Fig. 9-7).

**SMALL CARDIAC VEIN.** The small cardiac vein courses in the coronary sulcus between the right atrium and ventricle. It flows into the right extremity of the coronary sinus,

<sup>1</sup>Adam C. Thebesius (1686-1732): A German physician and anatomist.

FIG. 9-7. Base and diaphragmatic surface of heart.

near the site where the coronary sinus terminates in the right atrium (Fig. 9-7). The small cardiac vein receives blood from the back of the right atrium and ventricle. The **right marginal vein**, which ascends from near the apex and along the right margin of the heart, joins the small cardiac vein in the coronary sulcus, or opens directly into the right atrium.

**MIDDLE CARDIAC VEIN.** The middle cardiac vein commences at the apex of the heart, ascends in the posterior interventricular sulcus, receives tributaries from both ventricles, and ends in the coronary sinus near its right extremity (Fig. 9-7).

**POSTERIOR VEIN OF THE LEFT VENTRICLE.** Ascending along the diaphragmatic surface of the left ventricle, the posterior vein of the left ventricle accompanies the circumflex branch of the left coronary artery. Usually it opens into the coronary sinus to the left of the middle cardiac vein, but it may course farther to the left and open into the great cardiac vein (Fig. 9-7).

**OBLIQUE VEIN OF THE LEFT ATRIUM.** The oblique vein of the left atrium is a small vessel that descends obliquely on the back of the left atrium and ends in the coronary sinus near its left extremity (Fig. 9-7). It is continuous superiorly with the **ligament of the left vena cava**, and the two structures form the remnant of the left common cardinal vein.

Several cardiac veins do not end in the coronary sinus, but are directed into the chambers of the heart. These are the:

Anterior cardiac veins  
Smallest cardiac veins

#### ANTERIOR CARDIAC VEINS

The anterior cardiac veins consist of three or four small vessels that collect blood from the ventral aspect of the right ventricle and open into the right atrium. The right marginal vein frequently opens into the right atrium, and is therefore sometimes regarded as belonging to this group.

#### SMALLEST CARDIAC VEINS

These vessels (also called the *venae cordis minimi*) consist of a number of minute veins that arise in the muscular wall of the heart.

Most of them open into the atria, but a few end in the ventricles.

## Superior Vena Cava and its Tributaries

Draining into the superior vena cava are venous tributaries that collect blood from the head, neck, upper extremity, the thorax (including the thoracic wall), and even from much of the abdominal wall.

#### SUPERIOR VENA CAVA

The superior vena cava drains venous blood from the superior half of the body (Fig. 9-8). Its caliber of about 2 cm in diameter is second in size in the human body only to the inferior vena cava, which is slightly larger. The superior vena cava measures about 7 cm in length and is formed by the junction of the two brachiocephalic veins at the level of the first intercostal space, close behind the sternum on the right side. From this junction the superior vena cava transports blood inferiorly, lying deep to the second rib cartilage and intercostal space at the right border of the sternum, and empties into the upper part of the right atrium at the level of the third right costal cartilage. As it descends, the superior vena cava curves gently with its convexity to the right. The part of the vessel nearer the heart, amounting to about half its length, lies within the pericardial sac and it is covered by the serous pericardium.

**RELATIONS OF THE SUPERIOR VENA CAVA.** *Anterior* to the superior vena cava are the anterior margins of the right lung and pleura, with the pericardium intervening below. These separate it from the first and second intercostal spaces and from the second and third right costal cartilages. *Posterior* to it are the root of the right lung and the right vagus nerve. *On the right side* of the superior vena cava are the phrenic nerve and right pleura, and *on its left side*, is the commencement of the brachiocephalic artery and the ascending aorta, the latter overlapping the large vein. Just before piercing the pericardium, the superior vena cava receives the azygos vein and several small veins from the pericardium and other structures in the mediastinum. The superior vena cava has no valves.

**VARIATIONS IN THE SUPERIOR VENA CAVA.** At times the brachiocephalic veins open separately into the right atrium. In these cases the right brachioce-

**FIG. 9-8.** The large veins of the body. Note that the portal system of veins in the abdomen is represented in black. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, Urban and Schwarzenberg, 1975.)

phalic vein follows the normal course of the superior vena cava, while the left vein, called the **left superior vena cava**, passes ventral to the root of the left lung, and turning to the dorsum of the heart, ends in the right atrium. This occasional condition in the adult is due to the persistence of the early fetal condition (see Fig. 9-1, *C* and *D*), but is normal in adult birds and some mammals. In some instances of persistent left superior vena cava, a small branch may interconnect the two large veins.

#### TRIBUTARIES OF THE SUPERIOR VENA CAVA.

The two brachiocephalic veins join to form

the superior vena cava (Fig. 9-8). Additionally, the superior vena cava receives the azygos vein and several small veins from the mediastinum and pericardium. Further discussion of the tributaries of the superior vena cava relates to its regional drainage. Thus, the following sections are described sequentially:

Veins of the head and neck  
Veins of the upper limb  
Veins of the thorax

**VEINS OF THE HEAD AND NECK**

The veins of the head and neck may be divided into the following groups:

- Veins of the face
  - Superficial veins of the face
  - Deep veins of the face
- Veins of the cranium
  - Veins of the brain
  - Sinuses of the dura mater
  - Diploic veins
  - Emissary veins
- Veins of the neck
  - External jugular vein
  - Internal jugular vein
  - Vertebral vein

**Superficial Veins of the Face**

- Facial
- Superficial temporal
- Posterior auricular
- Occipital
- Retromandibular

These veins are tributaries of the internal and external jugular veins.

**FACIAL VEIN**

The facial vein drains blood from the superficial structures of the face (Figs. 9-9 and 9-10). Its first part, named the **angular vein**,

**FIG. 9-9.** The superficial veins of the head and neck.

begins at the medial angle of the eye by a union of the supratrochlear and supraorbital veins. It accompanies the facial artery along the lateral border of the nose, but has a less tortuous course. Descending on the face, deep to the zygomaticus major and minor muscles, the facial vein follows the border of the masseter muscle to the inferior border of the body of the mandible. It then curves around this bone to enter the neck. In the neck, the facial vein communicates with the anterior jugular vein and with the external jugular before emptying into the internal jugular at about the level of the hyoid bone. Formerly, the communication with the external jugular was named the *posterior facial* and the segment emptying into the internal jugular was named the *common facial* vein. The facial vein anastomoses with the cavernous sinus by way of the angular, supraorbital, and superior ophthalmic veins (Fig. 9-10), and also by way of its tributary, the **deep facial vein**, to the pterygoid plexus and inferior ophthalmic vein.

**CLINICAL CORRELATION.** The facial vein has no valves. In cases of infections about the nose and mouth, the blood in the vein may become thrombosed. An infected thrombus can progress against the flow of blood, finally reaching the cavernous sinus through its anastomoses and causing meningitis.

**ANGULAR VEIN.** The angular vein, formed by the junction of the supratrochlear and supraorbital veins at the root of the nose, becomes the facial vein near the level of the zygomaticus major muscle (Fig. 9-9). During its course the angular vein receives the following tributaries:

**superior palpebral vein**, which arises in the upper eyelid and opens into the lateral aspect of the angular vein;

**inferior palpebral vein**, which arises in the lower eyelid and passes downward and medially to open into the angular vein; and

**external nasal veins**, which course upward and laterally from the alae of the nose and open into the angular vein (Fig. 9-9).

**SUPRATROCHLEAR VEIN.** The supratrochlear vein commences from a venous plexus on the forehead and scalp that communicates with the frontal tributaries of the superficial temporal vein (Fig. 9-9). It lies near the vein of the opposite side in its course to the root of the nose. At this site, the two supra-

trochlear veins communicate by means of a transverse nasal arch before each joins the supraorbital vein of that side. Occasionally the two supratrochlear veins join on the upper forehead to form a prominent single vein that bifurcates at the root of the nose and joins the two angular veins.

**SUPRAORBITAL VEIN.** The supraorbital vein also begins by anastomosing with a frontal tributary of the superficial temporal vein (Fig. 9-9). It lies superficial to the frontal belly of the occipitofrontalis muscle, which it drains, and joins the supratrochlear vein at the medial angle of the orbit. As it passes over the supraorbital notch in the frontal bone, the supraorbital vein forms an anastomosis with the superior ophthalmic vein, and it also receives the frontal diploic vein, which perforates a foramen at the bottom of the notch.

**DEEP FACIAL VEIN.** The deep facial vein empties into the facial vein where the zygomaticus major muscle crosses the anterior border of the masseter muscle (Figs. 9-9; 9-10). It begins as a large anastomosis with the pterygoid plexus (Fig. 9-10), and receives small tributaries from the buccinator, zygomaticus major, and masseter muscles, as well as from other neighboring structures.

Other tributaries of the facial vein as it courses across the face are:

**superior labial vein**, which is formed from a venous plexus on the upper lip and drains laterally and superiorly to join the facial vein (Fig. 9-9);

**inferior labial vein**, which is formed along the lower lip and drains laterally to the facial vein (Fig. 9-9);

**parotid veins**, which are small vessels that drain the parotid and masseteric regions and course medially to join the facial vein;

**external palatine vein**, which drains the soft palate near the superior pole of the tonsil. It courses downward and forward in the tonsillar bed, penetrates the superior constrictor muscle, and joins the facial vein just below the body of the mandible.

In the neck, the facial vein receives the:

**submental vein**, which courses posteriorly along the mylohyoid muscle to join the facial vein below the body of the mandible (Fig. 9-9); and

**submandibular vein**, which drains the submandibular gland and courses laterally to join the facial vein.

### SUPERFICIAL TEMPORAL VEIN

The superficial temporal vein begins from a broad plexus of veins on the vertex and side of the head, where it anastomoses with the supratrochlear, supraorbital, posterior auricular, and occipital veins (Fig. 9-9). Over the crown of the skull, it anastomoses with the superficial temporal vein of the other side. Anterior and posterior tributaries unite in front of the ear to form the trunk of the superficial temporal vein, which then crosses the posterior root of the zygomatic arch and enters the substance of the parotid gland. Here it unites with the maxillary vein to form the **retromandibular vein**.

**TRIBUTARIES OF THE SUPERFICIAL TEMPORAL VEIN.** The superficial temporal vein receives the following tributaries:

**middle temporal vein**, which receives smaller vessels in the lateral orbital region, courses deep to the temporal fascia, and joins the superficial temporal vein just above the zygomatic arch (Fig. 9-9);

**transverse facial vein**, which courses laterally across the face superficial to the masseter muscle and joins the superficial temporal vein at about the level of the ear lobe (Fig. 9-9); and

**anterior auricular vein**, which returns blood from the external ear and joins the superficial temporal vein from behind (Fig. 9-9).

### POSTERIOR AURICULAR VEIN

The posterior auricular vein begins on the side of the head from a venous plexus that includes anastomoses with the occipital and superficial temporal veins (Fig. 9-9). It descends behind the external ear and joins the retromandibular vein within or below the parotid gland to form the external jugular vein. The posterior auricular vein receives tributaries from the back of the ear and the **stylomastoid vein**.

### OCCIPITAL VEIN

The occipital vein begins in a plexus on the posterior part of the scalp, where it anastomoses with posterior auricular and superficial temporal venous tributaries (Fig. 9-9). From this plexus the occipital vein becomes a single vessel that courses with the occipital artery and greater occipital nerve, and with

them pierces the cranial attachment of the trapezius muscle. It enters the suboccipital triangle, and forming a plexus, joins the deep cervical and vertebral veins. The **parietal emissary vein** connects it with the superior sagittal sinus, the **mastoid emissary vein** connects it with the transverse sinus, and through the **occipital diploic vein** it is connected with the confluens sinuum. Occasionally the occipital vein follows the occipital artery as far as the carotid sheath and empties into the internal jugular, or it may join the posterior auricular vein and drain into the external jugular vein.

### RETROMANDIBULAR VEIN

The retromandibular vein is formed from the junction of the superficial temporal and maxillary veins (Figs. 9-9; 9-10). It courses through the substance of the parotid gland between the ramus of the mandible and the upper part of the anterior border of the sternocleidomastoid muscle. The retromandibular vein lies superficial to the external carotid artery, but deep to the facial nerve. The retromandibular vein has a large communicating branch with the facial vein that was formerly called the *posterior facial vein*, and the common trunk from these two veins was called the *common facial vein* (Fig. 9-10). It receives small tributaries from the parotid gland and the masseter muscle, and joins the posterior auricular vein to form the beginning of the **external jugular vein**.

### Deep Veins of the Face

Maxillary  
Pterygoid plexus

These veins are tributaries of the internal and external jugular veins.

### MAXILLARY VEIN

The maxillary vein is a short trunk that accompanies the first part of the maxillary artery; it passes backward between the neck of the mandible and the sphenomandibular ligament. It is formed by a confluence of the veins in the pterygoid plexus and ends by joining the superficial temporal vein to form the retromandibular vein (Fig. 9-10).

**PTERYGOID PLEXUS**

The pterygoid plexus is an extensive network of veins situated between the temporalis and lateral pterygoid muscles and between the two pterygoid muscles, and it extends outward between surrounding structures in the infratemporal fossa (Fig. 9-10). It receives tributaries that correspond to branches of the maxillary artery. These include the:

**inferior alveolar vein**, which drains the lower jaw and lower teeth;

**middle meningeal vein**, which drains the dura mater located within the cranial cavity;

**deep temporal veins**, through which the pterygoid plexus anastomoses with the temporal plexus;

**masseteric vein**, which drains the masseter muscle;

**buccal vein**, which drains the buccinator muscle;

**posterior superior alveolar veins**, which drain the upper posterior teeth and gums;

**pharyngeal veins**, which drain the superior pharyngeal constrictor and the upper pharynx;

**descending palatine vein**, which drains the palate;

**infraorbital vein**, which assists in the drainage of the inferior structures of the orbit and the infraorbital region of the face;

**vein of the pterygoid canal**, which links the pterygopalatine fossa with the cranial cavity; and

**sphenopalatine vein**, which helps to drain the nasal cavity and nasal septum.

The sphenopalatine vein, accompanying the artery, drains the veins of the nasal sep-

**FIG. 9-10.** Principal veins of face and orbit. Two labels in parentheses utilize old terminology for which new terms were not included in the *Nomina Anatomica*. (From Eycleshymer and Jones.)

tum and the extensive plexuses of the erectile tissue in the mucous membrane of the nasal conchae. Its tributaries anastomose with the inferior ophthalmic and ethmoidal veins and may communicate through the cribriform plate and foramen cecum of the ethmoid bone with the superior sagittal sinus.

The pterygoid plexus communicates with the cavernous sinus through the foramen of Vesalius, the rete foraminae ovalis, emissary veins of the foramen lacerum, and inferior ophthalmic vein. It communicates with the facial vein through the deep facial and angular veins.

### Veins of the Brain

The veins of the brain are tributaries of the venous sinuses that flow into the internal jugular veins. They possess no valves, and their walls, due to the absence of muscular tissue, are extremely thin. As they

leave the brain, they pierce the arachnoid membrane and the inner or meningeal layer of the dura mater, and open into the cranial venous sinuses. The veins of the brain do not accompany the arteries. They may be subdivided into the:

- Cerebral veins
- Cerebellar veins
- Veins of the brainstem

### CEREBRAL VEINS

The cerebral veins include both **external veins**, which drain the outer surfaces of the brain and empty into the venous sinuses, and the **internal veins**, which drain the inner parts of the cerebral hemispheres and empty into the great cerebral vein (of Galen<sup>1</sup>). The external veins are the **superior, superficial middle, and inferior cerebral veins**.

<sup>1</sup>Claudius Galen (120–210 A.D.): A Greek physician, physiologist, and anatomist who practiced in Rome.

**FIG. 9-11.** The superficial cerebral veins as seen from the right side of the brain. (From Crosby, E. C., Humphrey, T. and Lauer, E. W., *Correlative Anatomy of the Nervous System*, Macmillan Publishing Co., Inc., New York, 1962.)

### Superior Cerebral Veins

The superior cerebral veins, 10 to 16 in number, drain the superolateral and medial surfaces of the hemispheres (Fig. 9-11). Most are lodged in the sulci of the cerebral cortex, but some run across the gyri. All of the superior cerebral veins open into the superior sagittal sinus after a course of one or more centimeters in the dural wall. The anterior veins course nearly at right angles to the sinus, while the posterior and larger veins are directed more obliquely forward and open into the sinus in a direction opposed to the current of the blood contained within it (this may be of little functional significance).

### Superficial Middle Cerebral Vein

The superficial middle cerebral vein begins on the lateral surface of the hemisphere and usually ends in the cavernous sinus (Fig. 9-11). It drains most of the lateral surface of the cerebral cortex, and courses in the lateral (Sylvian) sulcus. Although there may be multiple veins of smaller diameter within the sulcus, the superficial middle cerebral vein anastomoses both superiorly toward the midline and inferolaterally over the temporal lobe. It is connected above with the superior sagittal sinus by way of the **superior anastomotic vein** (of Trolard<sup>1</sup>), which then becomes one of the superior cerebral veins that open into the sinus. Inferolaterally, the superficial middle cerebral vein is joined to the transverse sinus by the **inferior anastomotic vein** (of Labbé<sup>2</sup>). Thus, the superficial middle cerebral vein is directly connected with the cavernous, superior sagittal, and transverse venous sinuses of the skull.

### Inferior Cerebral Veins

The inferior cerebral veins are small and drain the inferior surfaces of the hemispheres (Fig. 9-11). Those on the orbital surface of the frontal lobe join the superior cerebral veins, and through these open into the superior sagittal sinus. Others, which drain the temporal lobe, anastomose with the middle cerebral and basal veins, and join the

cavernous, sphenoparietal, superior petrosal, and transverse sinuses.

Located more deeply in the brain and draining the internal structures of the cerebral hemispheres are the **great cerebral vein** and its principal tributaries, the **internal cerebral veins**, and the **basal vein**.

### Great Cerebral Vein

The great cerebral vein is formed by the union of the two internal cerebral veins (Figs. 9-12; 9-13). It is a short (about 2 cm) median trunk into which flow the veins that drain the deep, medially oriented structures of the basal ganglia, thalamus, hypothalamus, and midbrain. It curves posteriorly and upward around the splenium of the corpus callosum, and ends by joining the inferior sagittal sinus at the anterior extremity of the straight sinus.

**INTERNAL CEREBRAL VEINS.** The two internal cerebral veins drain the deep parts of the hemisphere (Figs. 9-12; 9-13). Each is formed near the interventricular foramen by the union of the **thalamostriate** and **choroid veins**. The internal cerebral veins run backward, parallel with one another, between the layers of the tela choroidea of the third ventricle, and beneath the splenium of the corpus callosum, where they unite to form the great cerebral vein. Just prior to their union, each internal cerebral vein receives the corresponding basal vein of that side.

**THALAMOSTRIATE VEIN.** The thalamostriate vein commences in the groove between the corpus striatum and thalamus, and receives numerous veins from both of these regions (Figs. 9-12; 9-13). On each side the thalamostriate vein unites behind the anterior columns of the fornix with the choroid vein, to form the corresponding internal cerebral vein.

**CHOROID VEIN.** The choroid vein courses along the entire length of the choroid plexus, and receives veins from the hippocampus, the fornix, and the corpus callosum. Ascending to the interventricular foramen (of Monro<sup>3</sup>), the choroid vein is joined by the thalamostriate vein to form the internal cerebral vein.

<sup>1</sup>Paulin Trolard (1842-1910): A French anatomist.

<sup>2</sup>Leon Labbé (1832-1916): A French surgeon (Paris).

<sup>3</sup>Alexander Monro II (1733-1817): A Scottish anatomist (Edinburgh).

**FIG. 9-12.** The internal cerebral veins and their tributaries draining the deep cerebral structures. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, Urban and Schwarzenberg, 1975.)

### BASAL VEIN

The basal vein is formed at the anterior perforated substance by the union of a small **anterior cerebral vein** which accompanies the anterior cerebral artery, the **deep middle cerebral vein** which receives tributaries from the insula and neighboring gyri and runs in the lower part of the lateral cerebral sulcus, and the **inferior striate veins** which leave the corpus striatum through the anterior perforated substance (Fig. 9-13). The basal vein passes posteriorly around the cerebral peduncle, and ends either in the internal cerebral vein near its junction with the great cerebral vein, or in the great cerebral vein itself. It receives tributaries from the interpeduncular fossa, the inferior horn of

the lateral ventricle, the parahippocampal gyrus, and the midbrain.

### CEREBELLAR VEINS

The cerebellar veins are located on the surface of the cerebellum and consist of two sets, superior and inferior. Certain of the **superior cerebellar veins** pass forward and medially, across the superior vermis, and end in the straight sinus or in the great cerebral vein, while others course laterally to the transverse and superior petrosal sinuses. The **inferior cerebellar veins** are larger than the superior cerebellar; some course anteriorly and laterally and end in the superior petrosal or transverse sinuses, while others

**FIG. 9-13.** Midsagittal view of the deeply located veins of the cerebrum. Note the relationship of the internal cerebral veins, the great cerebral vein, and the straight sinus. (Adapted from Truex, R. C. and Carpenter, M. B., *Human Neuroanatomy*, 6th ed., Williams and Wilkins, Baltimore, 1969.)

course directly backward and open into the occipital sinus.

#### VEINS OF THE BRAINSTEM

The veins of the midbrain, pons, and medulla form a superficial plexus which lies deep to the arteries. From the plexus anterior and posterior median longitudinal channels form along the *medulla oblongata*. The anterior vein drains superiorly into the pontine plexus, inferiorly into the vertebral veins and the corresponding veins of the spinal cord, and laterally into radicular veins which leave the cranial cavity with the lower cranial nerves. The posterior vein drains into the inferior petrosal and basilar sinuses, as well as along the cranial nerve rootlets. Over the pons, the superficial venous channels form more laterally situated longitudinal veins. These drain laterally into the inferior petrosal sinuses or through the foramina with the cranial nerves. The venous drainage of the midbrain is directed

superiorly toward the great cerebral vein or the basal vein.

#### *Sinuses of the Dura Mater*

The sinuses of the dura mater are venous channels which drain blood from the brain and the bones that form the cranial cavity and carry it into the internal jugular vein. Situated between the two layers of the dura mater, they are devoid of valves but are lined by endothelium continuous with that of the veins into which they drain. They may be divided into a posterosuperior and an anteroinferior group.

The **posterosuperior group** of intracranial venous sinuses consists of the following:

- Superior sagittal sinus
- Inferior sagittal sinus
- Straight sinus
- Transverse sinuses
- Sigmoid sinuses
- Petrosquamous sinuses
- Occipital sinus
- Confluence of sinuses

**FIG. 9-14.** Superior sagittal sinus laid open after removal of the skull cap. The fibrous cords (of Willis) are clearly seen. The venous lacunae are also well shown: from two of them probes have been passed into the superior sagittal sinus. (From Poirier and Charpy.)

### SUPERIOR SAGITTAL SINUS

The superior sagittal sinus occupies the attached convex margin of the falx cerebri (Figs. 9-14; 9-15; 9-19). Commencing at the foramen cecum, through which it may receive a vein from the nasal cavity, the sinus is directed posteriorly, grooving the inner surface of the frontal bone, the adjacent margins of the two parietal bones, and the inner aspect of the squamous part of the occipital bone along the superior part of the cruciate eminence. Near the internal occipital protuberance, it deviates to one side, usually the right, and is continued as the corresponding transverse sinus. The superior sagittal sinus is triangular in cross section, and gradually enlarges as it passes posteriorly. Its inner surface presents the openings of the superior cerebral veins. Their orifices are concealed by fibrous folds and numerous fibrous bands (chords of Willis<sup>1</sup>) that extend

transversely across the inferior angle of the sinus (Fig. 9-14). Small openings in the wall communicate with irregularly shaped spaces, called **lateral venous lacunae**, in the dura mater near the sinus. There are usually three lacunae on each side, a small frontal, a large parietal, and an occipital which is intermediate in size. Most of the cerebral veins from the outer surface of the hemisphere open into these lacunae, and numerous **arachnoid granulations** (Pacchionian<sup>2</sup> bodies) project into them. These latter structures, evaginations of arachnoid mesothelium into the sinus, communicate with the subarachnoid space, and provide a pathway by which cerebrospinal fluid can flow directly into the venous blood. The superior sagittal sinus receives the superior cerebral veins and veins from the diploë, and near the posterior extremity of the sagittal suture, also the anastomosing emissary veins from the pericranium, which pass through the

<sup>1</sup>Thomas Willis (1621-1675): An English physician (London).

<sup>2</sup>Antonio Pacchioni (1665-1726): An Italian anatomist (Rome).

parietal foramina, and veins from the dura mater. Numerous anastomoses exist between this sinus and the veins of the nose and scalp.

### INFERIOR SAGITTAL SINUS

The inferior sagittal sinus is contained in the posterior half or two-thirds of the free margin of the falx cerebri. This is found in the deepest region of the longitudinal fissure that separates the two hemispheres of the brain, and just above the white commissure, called the corpus callosum, which interconnects the two hemispheres across the midline. The inferior sagittal sinus is cylindrical, increases in size as it passes posteriorly, and ends in the straight sinus (Figs. 9-15; 9-19). It receives several veins from the falx cerebri, and occasionally a few from the medial surface of the hemispheres.

### STRAIGHT SINUS

The straight sinus is situated at the line of junction of the falx cerebri and the tentorium cerebelli (Figs. 9-13; 9-15; 9-19). It is triangular in cross section, and it enlarges as it proceeds posteriorly from the end of the inferior sagittal sinus. It opens into the transverse sinus of the side opposite that in which the superior sagittal sinus terminates. Be-

sides receiving blood from the inferior sagittal sinus, the straight sinus receives the great cerebral vein and the superior cerebellar veins. A few transverse fibrous bands cross its interior.

### TRANSVERSE SINUSES

The transverse sinuses are large and begin at the internal occipital protuberance (Figs. 9-15; 9-16; 9-19). One, generally the right, is the direct continuation of the superior sagittal sinus, the other of the straight sinus. Each transverse sinus passes horizontally lateralward and then forward, describing a slight curve, to the base of the petrous portion of the temporal bone. In this part of its course, it lies in the attached margin of the tentorium cerebelli. As it leaves the tentorium, it becomes the sigmoid sinus. The transverse sinuses are frequently of unequal size, the one formed by the superior sagittal sinus being the larger. At the base of the petrous portion of the temporal bone, where the transverse sinuses become the sigmoid sinuses, they receive the superior petrosal sinuses. During their course, the transverse sinuses receive some of the inferior cerebral veins and the inferior anastomotic veins from the cerebral cortex, and some of the inferior cerebellar veins, as well as the posterior temporal and occipital diploic veins.

FIG. 9-15. Sagittal section of the skull with the brain removed, showing the sinuses of the dura.

## SIGMOID SINUSES

The sigmoid sinuses are directly continuous with the transverse sinuses and commence where the transverse sinuses emerge from the tentorium cerebelli. Each sigmoid sinus curves inferiorly and medially in an S-shaped manner, in order to reach the posterior part of the jugular foramen, where it ends in the internal jugular vein (Fig. 9-16). In its course it rests initially on the mastoid part of the temporal bone, and then just before its termination, on the jugular process of the occipital bone. As it passes through the jugular foramen, the sigmoid sinus is separated by the vagus and spinal accessory nerves from the inferior petrosal sinus, which emerges through the anterior part of the jugular foramen.

## PETROSQUAMOUS SINUSES

The petrosquamous sinuses are found only occasionally. When present, each is located in a groove that courses along the junction of the squamous and petrous parts of the temporal bone. On each side this sinus opens posteriorly into the transverse sinus, close to where the latter becomes the sigmoid sinus. Anteriorly the petrosquamous sinus communicates with the retromandibular vein behind the ramus of the mandible.

## OCCIPITAL SINUS

The occipital sinus is one of the smallest of the cranial sinuses (Figs. 9-15; 9-19). It is situated in or near the midline, along the attached margin of the falx cerebelli, and is generally single but occasionally paired. It commences around the margin of the foramen magnum by several small venous channels, one of which joins the terminal part of the sigmoid sinus. Inferiorly it communicates with the internal vertebral venous plexuses, and superiorly it opens into one of the transverse sinuses or, more frequently, into the confluence of sinuses.

## CONFLUENCE OF SINUSES

The confluence of sinuses (also known as the torcular Herophili<sup>1</sup>) is the dilated junction of three tributary sinuses, the superior

sagittal, the straight, and the occipital, with the two large transverse sinuses (Fig. 9-15). It is situated on the inner surface of the cranium, usually just to the right of the internal occipital protuberance. The direction of currents within the confluence is such that the right transverse sinus usually receives the greater part of its blood from the superior sagittal sinus, and the left transverse sinus receives blood from the straight sinus.

The **anteroinferior group** of intracranial venous sinuses includes the following:

- Cavernous sinuses
- Ophthalmic veins
- Sphenoparietal sinuses
- Intercavernous sinus
- Superior petrosal sinuses
- Inferior petrosal sinuses
- Basilar plexus

## CAVERNOUS SINUSES

The cavernous sinuses are situated to the right and left of the body of the sphenoid bone, and communicate with each other both in front of and behind the hypophysis (Fig. 9-16). They are about 1 cm wide and are traversed by numerous interlacing fibrous filaments which present them with irregular venous spaces internally, and a trabeculated, spongy character that slows the flow of venous blood. They are larger behind than in front, and each sinus extends about 2 cm from the superior orbital fissure anteriorly to the apex of the petrous portion of the temporal bone posteriorly. Each cavernous sinus drains posteriorly into the superior petrosal and inferior petrosal sinuses.

Along the *medial wall* of each cavernous sinus courses the internal carotid artery, surrounded by the carotid plexus of sympathetic nerve fibers (Fig. 9-17), and just inferior and lateral to the artery is found the abducens nerve. On the *lateral wall* of the sinus are the oculomotor and trochlear nerves, along with the ophthalmic and maxillary divisions of the trigeminal nerve (Fig. 9-17). These structures are separated from the blood flowing through the sinus by the endothelial lining of the sinus wall.

The cavernous sinus receives the superior and inferior ophthalmic veins, the superficial middle cerebral vein, several of the inferior cerebral veins, and the small sphenoparietal sinus. It communicates with the transverse sinus by means of the superior

<sup>1</sup>Herophilus (about 350 B.C.): A Greek physician and anatomist, who worked in Alexandria, Egypt.

FIG. 9-16. The venous sinuses at the base of the skull.

petrosal sinus; with the *internal jugular vein* by way of the *inferior petrosal sinus*; with the *pterygoid plexus* by veins that pass through the *sphenoidal emissary foramen* (of Vesalius<sup>1</sup>), the *foramen ovale*, and *foramen lacerum*; and with the *angular and facial veins* through the *superior ophthalmic vein*. The two *cavernous sinuses* anastomose with each other through the *anterior and posterior intercavernous sinuses*.

**Superior Ophthalmic Vein**

The *superior ophthalmic vein* begins at the medial angle of the upper eyelid by a confluence of tributaries of the *supratrochlear*, *supraorbital*, and *angular veins* (Figs.

9-16; 9-19). It passes posteriorly through the superior part of the orbit, and receives tributaries that correspond to the branches of the *ophthalmic artery*. Forming a short single trunk, it passes between the two heads of the

FIG. 9-17. Oblique section through the cavernous sinus.

<sup>1</sup>Andreas Vesalius (1514-1564): A great Flemish anatomist who did his finest work in Padua, Italy.

lateral rectus muscle and then through the medial part of the superior orbital fissure below the abducens nerve, and opens into the cavernous sinus.

#### Inferior Ophthalmic Vein

The inferior ophthalmic vein begins in a venous network on the anterior part of the floor and medial wall of the orbit (Fig. 9-19). It receives veins from the inferior rectus and inferior oblique muscles, as well as from the lacrimal sac and eyelids. Coursing posteriorly in the inferior part of the orbit, it divides into two branches. One of these passes through the inferior orbital fissure and joins the pterygoid venous plexus. The other enters the cranial cavity through the superior orbital fissure and ends in the cavernous sinus, either separately, or more frequently in common with the superior ophthalmic vein.

#### SPHENOPARIETAL SINUSES

Each of the two sphenoparietal sinuses, one on each side, begins from a small meningeal vein near the lateral tip of the lesser wing of the sphenoid bone. It then courses medially in a groove on the inferior surface of the lesser wing of the sphenoid bone and drains into the anterior part of the cavernous sinus. In addition to receiving a few small meningeal venous tributaries, it usually receives the anterior temporal diploic vein.

#### INTERCAVERNOUS SINUSES

The anterior and posterior intercavernous sinuses interconnect the cavernous sinuses across the midline. The anterior intercavernous sinus passes in front of the hypophysis, while the posterior passes behind the gland (Fig. 9-16). Together with the cavernous sinuses, they form a venous circle, sometimes called the **circular sinus**, around the hypophysis. The anterior intercavernous sinus is usually the larger of the two, but either one may be absent.

#### SUPERIOR PETROSAL SINUSES

The superior petrosal sinuses are small and narrow, and on each side they connect the cavernous with the transverse sinus (Figs. 9-15; 9-16; 9-19). Each superior petrosal

sinus courses laterally and backward from the posterior end of the cavernous sinus. Passing over the trigeminal nerve, it lies in the attached margin of the tentorium cerebelli, along a groove in the superior border of the petrous portion of the temporal bone. It joins the transverse sinus where the latter curves downward and becomes the sigmoid sinus on the inner surface of the mastoid part of the temporal. It receives certain of the cerebellar and inferior cerebral veins, and veins from the tympanic cavity.

#### INFERIOR PETROSAL SINUSES

Each of the two inferior petrosal sinuses is situated in the corresponding inferior petrosal sulcus that is formed by the junction of the petrous part of the temporal bone and the basilar part of the occipital bone (Figs. 9-15; 9-16; 9-19). Commencing at the postero-inferior part of the cavernous sinus, the inferior petrosal sinus passes to the anterior part of the jugular foramen, and it ends in the superior bulb of the *internal jugular vein*. The inferior petrosal sinus receives the **labyrinthine veins**, and also veins from the medulla oblongata, pons, and inferior surface of the cerebellum.

The relationship of the vessels and nerves passing through the jugular foramen is as follows: the inferior petrosal sinus lies anteromedially, with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downward and backward; the sigmoid sinus is situated at the lateral and posterior part of the foramen, with a meningeal branch of the occipital artery; between the two sinuses are the glossopharyngeal, vagus, and accessory nerves. These three sets of structures are separated by two processes of fibrous tissue. The junction of the inferior petrosal sinus and the internal jugular vein takes place on the lateral aspect of the nerves.

#### BASILAR PLEXUS

The basilar plexus consists of several interlacing venous channels located between the layers of the dura mater over the basilar part of the occipital bone (Fig. 9-16). It serves to connect the two inferior petrosal sinuses, and it communicates with the anterior vertebral venous plexus.

### Diploic Veins

The diploë of the cranial bones contain bone marrow and are drained by venous channels called the diploic veins. These veins are large and at irregular intervals exhibit pouch-like dilatations. Their walls are thin, consisting only of endothelium resting on a layer of elastic tissue. While the cranial bones are separated from one another, these veins are confined to particular bones, but when the sutures are obliterated, the veins unite and generally increase in size. Thus, they are enlarged in the elderly, but virtually nonexistent in the newborn, only gradually developing during early childhood. The diploic veins communicate with the meningeal veins and the sinuses of the dura mater, with the veins of the pericranium, and with each other. Usually the following diploic veins are found in the skull:

Frontal  
Anterior temporal  
Posterior temporal  
Occipital

#### FRONTAL DIPLOIC VEIN

The frontal diploic vein is found in the anterior part of the frontal bone (Fig. 9-18). Through the inner table of the skull, it communicates with the superior sagittal sinus. The veins of the two sides usually join ante-

riorly to form a single vessel, which perforates the outer table in the roof of the supraorbital notch and anastomoses with the supraorbital vein.

#### ANTERIOR TEMPORAL DIPLOIC VEIN

There are usually two anterior temporal diploic veins, one found in front of the coronal suture in the frontal bone, and the other behind the suture in the parietal bone (Fig. 9-18). Internally they communicate with the sphenoparietal sinus, while externally they anastomose with one of the deep temporal veins through an aperture in the great wing of the sphenoid bone.

#### POSTERIOR TEMPORAL DIPLOIC VEIN

The posterior temporal diploic vein courses downward in the parietal bone toward the mastoid region of the temporal bone (Fig. 9-18). It either perforates the inner table through an aperture at the mastoid angle of the parietal bone, or it courses through the mastoid foramen and terminates in the transverse sinus.

#### OCCIPITAL DIPLOIC VEIN

The occipital diploic vein, the largest of the diploic veins, is confined to the occipital bone (Fig. 9-18). It opens either externally

Fig. 9-18. The diploic veins displayed after removal of the outer table of the skull.

into the occipital vein, or internally into the transverse sinus or the confluence of sinuses.

### Emissary Veins

The emissary veins pass through various foramina and openings in the cranial wall and establish anastomoses between the si-

nuses of the dura inside the skull and the veins on the exterior of the skull (Fig. 9-19). Some of the following emissary veins are always present, others only occasionally.

**MASTOID EMISSARY VEIN.** The mastoid emissary vein is usually present. It courses through the mastoid foramen and may tra-

**Fig. 9-19.** The veins of the head and neck projected onto the skull and brain. The cerebral ventricles are shown in red. The extracranial portions of the veins are shown in solid blue, while the intracranial portions of the veins are in hatched blue. Numbers identify the foramina through which veins traverse the cranium. 1, Superior orbital fissure. 2, Inferior orbital fissure. 3, Foramen ovale. 4, Foramen spinosum. 5, Foramen lacerum. 6, Carotid canal. 7, Jugular foramen. 8, Hypoglossal canal. 9, Condylar canal. Black inverted crescents indicate openings through which emissary veins pass. (From Eycleshymer and Jones.)

verse a diploic vein for a short distance, connecting the sigmoid sinus with the posterior auricular or with the occipital vein.

**OCCIPITAL EMISSARY VEIN.** The occipital emissary vein courses through a small foramen at the occipital protuberance and links the confluence of sinuses with the occipital vein.

**PARIETAL EMISSARY VEIN.** The parietal emissary vein passes through the parietal foramen, anastomoses with the diploic veins, and interconnects the superior sagittal sinus with the veins of the scalp.

**VENOUS PLEXUS OF THE HYPOGLOSSAL CANAL.** This network of small veins traverses the hypoglossal canal and joins the sigmoid sinus with the vertebral vein or the internal jugular vein.

**CONDYLAR EMISSARY VEIN.** The condylar emissary vein is inconstant, but when present, it passes through the condylar canal and connects the sigmoid sinus with the deep veins in the upper neck.

**VENOUS PLEXUS OF THE FORAMEN OVALE.** This plexus of small veins interconnects the cavernous sinus with the pterygoid plexus through the foramen ovale.

**EMISSARY VEINS OF THE FORAMEN LACERUM.** Two or three small veins course through the foramen lacerum and connect the cavernous sinus with the pterygoid plexus.

**EMISSARY VEIN OF THE SPHENOID FORAMEN.** In about half of the skulls, an emissary vein courses through the sphenoidal foramen (of Vesalius), which also connects the cavernous sinus with the pterygoid plexus.

**INTERNAL CAROTID VENOUS PLEXUS.** An internal carotid plexus of veins accompanies the internal carotid artery and traverses the carotid canal between the cavernous sinus and the internal jugular vein.

**EMISSARY VEIN OF THE FORAMEN CECUM.** In some specimens a vein is transmitted through the foramen cecum, which connects the superior sagittal sinus with the veins of the nasal cavity.

Other anastomoses between the dural sinus and veins outside the cranial cavity that are not classed as emissary veins are the connection between the cavernous sinus and the facial vein through the superior ophthalmic and angular veins, and the communication between the inferior petrosal sinus and the vertebral veins by way of the basilar plexus.

## *External Jugular Vein*

The **external jugular vein** is one of three large veins that course in the neck and return blood from structures in the cranial cavity, face, and neck. The other two are the **vertebral vein** and the **internal jugular vein**. The external jugular vein flows into the subclavian vein, as does the vertebral vein, whereas the internal jugular vein is a tributary of the brachiocephalic vein.

The external jugular vein receives the greater part of the blood from the exterior of the cranium, including the scalp and the superficial and deep regions of the face. It is formed by the junction of the retromandibular and the posterior auricular veins (Figs. 9-20; 9-22). It commences in the substance of the parotid gland, on a level with the angle of the mandible. Descending perpendicularly in the neck, the external jugular vein obliquely crosses the superficial surface of the sternocleidomastoid muscle, along a line between the angle of the mandible and the middle of the clavicle. At the clavicle, it lies near the posterior border of the sternocleidomastoid muscle, and within the subclavian triangle it perforates the deep fascia and ends in the subclavian vein, lateral or ventral to the anterior scalene muscle. It is separated from the sternocleidomastoid muscle by the investing layer of deep cervical fascia, and is covered by the platysma, the superficial fascia, and skin. The external jugular vein crosses the transverse cervical nerve, and its upper half courses parallel to the great auricular nerve. The vein varies in size, in inverse proportion to the other veins of the neck; it is occasionally doubled. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein; the upper pair in most cases is about 4 cm above the clavicle. The portion of vein located between the two sets of valves is often dilated, and is sometimes termed the **sinus of the external jugular vein**. These valves do not prevent the regurgitation of blood, or the passage of injected substances distally.

**TRIBUTARIES OF THE EXTERNAL JUGULAR VEIN.** The external jugular vein receives the posterior external jugular vein, and near its termination, the anterior jugular, transverse scapular, and suprascapular veins. It also is joined by a large communicating branch

from the internal jugular vein, and occasionally it receives the occipital vein.

### POSTERIOR EXTERNAL JUGULAR VEIN

The posterior external jugular vein begins in the occipital region and returns blood from the skin and superficial muscles in the upper and posterior part of the neck. It lies between the splenius and trapezius muscles (Fig. 9-23), runs down the posterior part of the neck, and opens into the middle third of the external jugular vein.

### Anterior Jugular Vein

The anterior jugular vein begins near the hyoid bone, and is formed by the confluence of several superficial veins from the submandibular region (Fig. 9-20). It descends between the midline of the neck and the anterior border of the sternocleidomastoid muscle. In the lower neck, the anterior jugular vein passes deep to the sternocleidomas-

toid muscle and opens into the terminal part of the external jugular, or in some instances, into the subclavian vein (Fig. 9-20). It varies considerably in size, usually in inverse proportion to the size of the external jugular vein. Most frequently there are two anterior jugular veins, a right and left, but sometimes only one. It usually receives tributaries from some laryngeal veins and occasionally from a small thyroid vein, and it communicates with the internal jugular vein. Just above the sternum the two anterior jugular veins are united by a transverse trunk and form the **jugular venous arch**, which receives tributaries from the inferior thyroid veins. The anterior jugular vein contains no valves.

### TRANSVERSE CERVICAL VEIN

The transverse cervical vein forms from tributaries that drain from beneath the trapezius (Figs. 9-20; 9-22). It is directed antero-medially, across the posterior triangle of the neck, and opens into the external jugular

**Fig. 9-20.** The superficial veins of the neck. The right sternocleidomastoid muscle has been removed to reveal the course of the internal jugular vein. (After Sobotta.)

vein near its termination, but it may drain into the subclavian vein. It usually accompanies the transverse cervical artery.

#### SUPRASCAPULAR VEIN

The suprascapular (or transverse scapular) vein accompanies the artery of the same name and usually opens into the external jugular near its termination. It may empty into the subclavian vein.

#### *Internal Jugular Vein*

The internal jugular vein collects blood from the brain, the superficial parts of the face, and the neck (Figs. 9-20; 9-22). It is directly continuous with the sigmoid sinus in the posterior compartment of the jugular foramen at the base of the skull. At its origin is a dilatation called the **superior jugular bulb**. The internal jugular vein courses downward in the neck, lying at first lateral to the internal carotid artery, and then lateral to the common carotid artery. At the root of the neck, it unites with the subclavian vein to form the brachiocephalic vein. A little above its termination is a second dilatation, the **inferior jugular bulb**.

Superiorly near its origin, the internal jugular vein lies on the rectus capitis lateralis muscle, and behind the internal carotid artery and the nerves emerging from the jugular foramen. Just above the posterior belly of the digastric muscle, the internal jugular vein and the internal carotid artery lie nearly in the same plane as the glossopharyngeal and hypoglossal nerves, which pass anteriorly between them. The vagus nerve descends between the vein and the artery, and the accessory nerve runs obliquely backward, superficial to the internal jugular vein and toward the sternocleidomastoid muscle. It is frequently stated that the internal jugular vein is surrounded throughout its course by the carotid sheath. The vein, however, is usually superficial to the sheath, which in fact does surround the internal carotid artery and vagus nerve. At the root of the neck, the right internal jugular vein is placed at a little distance from the common carotid artery, and crosses the first part of the subclavian artery, whereas the left internal jugular vein usually overlaps the common carotid artery. The left vein is generally smaller than the right, and each contains a

pair of valves that are placed about 2.5 cm above the termination of the vessel.

**TRIBUTARIES OF THE INTERNAL JUGULAR VEIN.** During its course, the internal jugular vein receives the inferior petrosal sinus and the facial, lingual, pharyngeal, superior and middle thyroid, and sometimes occipital veins. The thoracic duct on the left side and the right lymphatic duct on the right side open into the angle of union of the internal jugular and subclavian veins.

Because the inferior petrosal sinus and the facial and occipital veins were described earlier in the chapter, they will not be elaborated on further here. However, note that the **inferior petrosal sinus** leaves the skull through the anterior part of the jugular foramen, and joins the superior bulb of the internal jugular vein; the **facial vein** joins the internal jugular vein just below the angle of the mandible; and the **occipital vein** usually joins the posterior auricular vein and flows into the external jugular vein, but at times it follows the course of the occipital artery and flows directly into the internal jugular vein near the level of the hyoid bone.

#### LINGUAL VEIN

The lingual vein opens into the internal jugular vein near the hyoid bone. It receives blood primarily from its **dorsal lingual** tributaries. Additionally, blood from the tip of the tongue drains into the **deep lingual** vein.

**DORSAL LINGUAL VEINS.** Two or more dorsal lingual veins drain the dorsum and sides of the tongue (Fig. 9-21). Coursing downward and posteriorly, they join together to form the lingual vein, which accompanies the lingual artery. The lingual vein then courses posteriorly between the genioglossus and hyoglossus muscles and empties into the internal jugular vein just above the greater horn of the hyoid bone.

**DEEP LINGUAL VEIN.** The deep lingual vein commences at the tip of the tongue, where it forms an anastomosis with the same vein from the opposite side (Fig. 9-21). Traveling downward and backward just deep to the mucous membrane of the tongue, it receives the small **sublingual vein**, and near the anterior border of the hyoglossus muscle, it becomes adjacent to the hypoglossal nerve. At this point it is called the **accompanying vein of the hypoglossal nerve**, also known as the **ranine vein**. Passing backward with the hy-

FIG. 9-21. Veins of the tongue. The hypoglossal nerve has been displaced downward. (From Testut.)

poglossal nerve along the lateral (superficial) border of the hyoglossus muscle, this vein usually opens into the facial vein, but it may join the lingual vein or even open directly into the internal jugular vein.

#### PHARYNGEAL VEINS

The pharyngeal veins begin in the pharyngeal plexus on the outer surface of the pharynx, and after receiving some posterior meningeal veins and the vein coursing with the artery of the pterygoid canal, they end in the internal jugular vein. They occasionally open into the facial, lingual, or superior thyroid vein.

#### SUPERIOR THYROID VEIN

The superior thyroid vein begins in the substance and on the surface of the thyroid gland by tributaries that correspond to the branches of the superior thyroid artery, and ends in the middle part of the internal jugular vein, just below the hyoid bone (Figs. 9-20; 9-22). It receives the superior laryngeal and cricothyroid veins. At times the superior thyroid vein opens into the facial vein.

#### MIDDLE THYROID VEIN

The middle thyroid vein collects blood from the lower lateral part of the thyroid gland, and is joined by some veins from the larynx and trachea. It crosses laterally in front of the common carotid artery and deep

to the strap muscles, and opens into the internal jugular vein just above the level of the lower border of the thyroid gland.

#### Vertebral Vein

The vertebral vein **does not** emerge from the cranial cavity through the foramen magnum with the vertebral artery. Instead, it is formed in the suboccipital triangle from numerous small tributaries that spring from the internal vertebral venous plexuses and leave the vertebral canal above the posterior arch of the atlas (Fig. 9-23). These vessels unite with small veins from the deep muscles in the upper part of the dorsal neck, and form a vessel that enters the foramen in the transverse process of the atlas. Forming a dense plexus around the vertebral artery, they descend in a canal formed by the transverse foramina of the cervical vertebrae. This plexus ends in a single trunk, the vertebral vein, which emerges usually from the transverse foramen of the sixth (but occasionally from the seventh) cervical vertebra. In the root of the neck, the vertebral artery opens into the dorsal part of the brachiocephalic vein near its origin, its opening being guarded by a pair of valves. On the right side, the vertebral vein crosses the first part of the subclavian artery.

**TRIBUTARIES OF THE VERTEBRAL VEIN.** The vertebral vein communicates with the sigmoid sinus by a vein that passes through the condylar canal, when that canal exists. It also receives tributaries from the occipital

**Fig. 9-22.** The internal jugular system of veins in the deeper neck. Note the superior middle and inferior thyroid veins. (After Sobotta.)

vein, the prevertebral muscles, the internal and external vertebral venous plexuses, and the anterior vertebral and the deep cervical veins. Near its termination it is sometimes joined by the first intercostal vein.

#### ANTERIOR VERTEBRAL VEIN

The anterior vertebral vein (ascending cervical vein) commences in a plexus around the transverse processes of the cranial cervical vertebrae (Fig. 9-23). It descends in the neck with the ascending cervical artery, between the anterior scalene and longus capitis muscles, and opens into the terminal part of the vertebral vein.

#### DEEP CERVICAL VEIN

The deep cervical vein accompanies its artery between the semispinalis capitis and cervicis (Fig. 9-23). It begins in the suboccipital region as communicating branches from the occipital vein and as small veins

from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spines of the cervical vertebrae, and terminates in the inferior part of the vertebral vein.

#### ACCESSORY VERTEBRAL VEIN

The accessory vertebral vein, when present, arises as a small vein from the venous plexus surrounding the vertebral artery, in the canal formed by the transverse foramina of the cervical vertebrae. It emerges from the transverse foramen of the seventh cervical vertebra, courses anteriorly in the lower neck, and opens into the terminal part of the vertebral vein.

#### VEINS OF THE UPPER LIMB

The veins of the upper limb can be divided into two sets, **superficial** and **deep**. Distinguished by their topographic position,

**FIG. 9-23.** The vertebral vein and other veins in the neck, lateral view. (From Poirier and Charpy.)

they anastomose with each other at frequent sites, and thus form several parallel channels of drainage from any single region. The superficial veins are distributed immediately beneath the skin, within the superficial fascia. The deep veins accompany the arteries, are the *venae comitantes*, and usually have the same name as their arteries. Both sets of veins are provided with valves, which are more numerous in the deep veins than in the superficial.

#### **Superficial Veins of the Upper Limb**

Two large veins, the cephalic and the basilic, receive blood from the smaller superficial veins of the upper limb, and convey it to the axillary vein and then into the subclavian and brachiocephalic veins (Fig. 9-24). The cephalic vein courses along the radial side of the forearm and the lateral side of the arm. The basilic vein occupies the ulnar aspect of the forearm and medial side of the arm. The **superficial veins of the upper limb** are:

- Cephalic
- Basilic
- Median antebrachial
- Venous network of the dorsal hand
- Superficial venous palmar arch

#### **CEPHALIC VEIN**

The cephalic vein begins on the radial aspect of the dorsal venous network of the hand (Fig. 9-24). As it ascends, it winds around the radial border of the forearm, thereby receiving tributaries from both palmar and dorsal surfaces of the hand. Just below the antecubital fossa, it communicates with the basilic vein by means of the **median cubital vein**, which also receives a branch from the deep forearm veins. The main stem of the cephalic vein then continues proximally, along the lateral side of the antecubital fossa in the groove between the brachioradialis and the biceps brachii muscles, where it crosses superficial to the lateral antebrachial cutaneous branch of the musculocutaneous nerve. Its ascent in the arm continues in the groove along the lateral border of the biceps brachii. In the proximal third of the arm, it passes between the pectoralis major and deltoid muscles, where it is accompanied by the deltoid branch of the thoracoacromial artery. From the interval between these two muscles and the clavicle, called the **deltopectoral triangle**, the cephalic vein passes behind the clavicular head of the pectoralis major muscle. It then pierces the clavipectoral fascia, and crossing the axillary artery, it enters the axillary vein

**Fig. 9-24.** The superficial veins of the upper limb. Note the radial or lateral course of the cephalic vein and the ulnar or medial ascent of the basilic vein.

just below the clavicle (Fig. 9-27). Sometimes it communicates with the external jugular vein by a tributary that ascends in front of the clavicle.

**ACCESSORY CEPHALIC VEIN.** The accessory cephalic vein arises either from a small tributary plexus on the dorsum of the forearm or from the ulnar side of the dorsal venous network (Fig. 9-24). It remains on the radial side of the cephalic vein and joins it just below the elbow. The accessory cephalic

vein may spring from the cephalic vein, proximal to the wrist, and join it once again higher in the forearm. A large oblique anastomosis frequently connects the basilic and cephalic veins on the back of the forearm.

### BASILIC VEIN

The basilic vein begins on the ulnar aspect of the dorsal venous network of the hand. It ascends on the posterior surface of the ulnar side of the forearm, and is inclined toward the anterior surface just below the elbow, where it is joined by the median cubital vein (Fig. 9-24). It then courses obliquely upward in the groove between the biceps brachii and pronator teres and crosses the brachial artery, from which it is separated by the bicipital aponeurosis. Filaments of the medial antebrachial cutaneous nerve pass both in front of and behind this portion of the vein. Continuing upward in the arm, the basilic vein then travels along the medial border of the biceps brachii. It perforates the deep fascia a little below the middle of the arm, and ascending on the medial side of the brachial artery to the lower border of the teres major, it joins the brachial vein to form the **axillary vein** (Fig. 9-27).

### MEDIAN ANTEBRACHIAL VEIN

The median antebrachial vein drains the venous plexus on the palmar surface of the hand (Fig. 9-24). It ascends slightly toward the ulnar side of the anterior forearm, and ends either in the basilic vein or in the median cubital vein. At times it divides into two vessels, one of which joins the basilic vein and the other the cephalic vein below the antecubital fossa. The median antebrachial vein also anastomoses with the deep veins of the forearm.

There is great variation in the pattern of the superficial veins of the forearm. Frequently there is a reciprocal relationship in the size of the cephalic and basilic veins. Either one may predominate or even be lacking. The median antebrachial vein may be absent as a definite vessel. The **median cubital vein** may split into a distinct Y, with one arm of the Y draining into the cephalic and the other into the basilic vein. In this case, one branch is called the **median cephalic vein**, the other the **median basilic vein**.

**CLINICAL CONSIDERATIONS.** The veins of the proximal forearm are usually the ones employed in venipuncture. One of the veins of the median cubital complex regularly has a large vessel anastomosing with the deep veins (Fig. 9-27). This anastomosis holds the superficial vein in place and prevents it from slipping away from the point of the needle.

#### VENOUS NETWORK OF THE DORSAL HAND

The venous network of the dorsal hand forms initially from **dorsal digital veins** which pass along the sides of the fingers. These are joined to one another by oblique communicating branches, and the digital veins from the adjacent sides of the fingers unite to form three **dorsal metacarpal veins** which end in the venous network on the

back of the hand (Fig. 9-25). The *radial part of the network* is joined by the dorsal digital vein from the radial side of the index finger and by the dorsal digital veins of the thumb; it is prolonged proximally as the **cephalic vein**. The *ulnar part of the network* receives the dorsal digital vein of the ulnar side of the little finger, and is continued proximally as the **basilic vein**. An anastomosing vein frequently makes an additional connection with either the cephalic or basilic vein in the middle of the forearm.

#### SUPERFICIAL VENOUS PALMAR ARCH

The superficial venous palmar arch is more delicate than the venous network of the dorsal hand and is formed by **palmar**

**FIG. 9-25.** The veins on the dorsum of the hand.

**digital veins** that drain into venous networks situated over the thenar and hypothenar eminences. These, in turn, flow proximally over the palmar surface of the wrist and help to form the **median antebrachial vein**. The palmar digital veins also are interconnected in the folds between the fingers to the venous network of the dorsal hand by the **intercapitular veins**.

### Deep Veins of the Upper Limb

The **deep veins** follow the course of the arteries, accompanying them as their **venae comitantes**. Accompanying veins are generally arranged in pairs, situated on both sides of the corresponding artery, and several short, transverse anastomotic channels generally interconnect them. The deep veins of the upper limb include the following:

- Deep veins of the hand
- Deep veins of the forearm
- Brachial veins
- Axillary veins
- Subclavian vein

### DEEP VEINS OF THE HAND

The superficial and deep palmar arterial arches are each accompanied by a pair of **venae comitantes** that form the **superficial and deep palmar venous arches** and receive the veins corresponding to the branches of the arterial arches. Thus, the **common palmar digital veins**, formed by the union of the **proper palmar digital veins**, open into the superficial venous arch, and the **palmar metacarpal veins** flow into the deep palmar venous arch. The **dorsal metacarpal veins** receive perforating branches from the palmar metacarpal veins, and end in the radial veins and the superficial veins on the dorsum of the wrist.

### DEEP VEINS OF THE FOREARM

The deep veins of the forearm are the **venae comitantes** of the radial and ulnar arteries and constitute the vessels into which the palmar venous arches flow. The deep venous palmar arch drains principally into the radial veins, while the superficial venous palmar arch drains into the ulnar veins. The radial and ulnar **venae comitantes** all unite at the bend of the elbow to form the **brachial veins** (Fig. 9-26). The radial veins are smaller

**FIG. 9-26.** The deep veins of the upper forearm and lower arm in the left upper limb.

than the ulnar, and also receive the dorsal metacarpal veins. The ulnar veins also receive small tributaries from the deep palmar venous arch and communicate with the superficial veins at the wrist. Near the elbow the ulnar veins receive the anterior and posterior interosseous veins and send a large communicating branch to the median cubital vein.

### BRACHIAL VEINS

The two brachial veins are placed on the medial and lateral sides of the brachial artery, and receive tributaries that correspond to the branches given off by the artery (Fig. 9-26). Near the lower margin of the subscapularis muscle, they join the axillary vein. The medial brachial vein frequently flows into the basilic vein. During the remainder of its ascent into the axillary vein, the basilic vein takes the place of the medial brachial accompanying vein. These deep

veins have numerous anastomoses, not only with each other, but also with the superficial veins.

### AXILLARY VEIN

The axillary vein begins at the junction of the basilic and brachial veins, which is located usually near the lower border of the teres major muscle, and it ends at the outer border of the first rib, where it becomes the subclavian vein (Fig. 9-27). In addition to the tributaries that correspond to the branches of the axillary artery, it receives the cephalic vein near its termination. It lies on the medial side of the artery, which it partly overlaps. Between the two vessels are the medial cord of the brachial plexus, the median, the ulnar, and the medial pectoral nerves. Adjacent to the axillary vein are the medial brachial and antebrachial cutaneous nerves, and closely related to the axillary neurovascular bundle are the lateral axillary lymph nodes. The axillary vein is provided with a pair of valves opposite the distal border of the subscapularis muscle, and valves also are found at the ends of the cephalic and subscapular veins.

### SUBCLAVIAN VEIN

The subclavian vein is the continuation of the axillary vein, and it extends from the lateral border of the first rib to the sternal end of the clavicle, where it unites with the internal jugular vein and forms the **brachiocephalic vein**. It is in relation anteriorly with the clavicle and subclavius muscle, and posteriorly and superiorly with the subclavian artery, from which it is separated medially by the anterior scalene muscle, and on the right side, by the phrenic nerve. Inferiorly it rests in a depression on the first rib and on the pleura. It usually is provided with a pair of valves that are situated about 2.5 cm from its termination. The subclavian vein occasionally ascends in the neck to the level of the third part of the subclavian artery, and at times passes with this vessel behind the anterior scalene muscle.

**TRIBUTARIES OF THE SUBCLAVIAN VEIN.** The subclavian vein usually receives only the external jugular vein, but sometimes it also receives the anterior jugular vein, and occasionally also a small tributary from the cephalic vein, which ascends ventral to the clavicle. At its angle of junction with the in-

**FIG. 9-27.** The veins of the right axilla, showing their relationship to the axillary artery and some of the nerves and muscles of the region.

ternal jugular, the *left subclavian vein* receives the **thoracic duct**, and the *right subclavian vein* receives the **right lymphatic duct**.

### VEINS OF THE THORAX

The special vein of the thorax that drains the blood from the thoracic wall and intercostal spaces is the **azygos vein** (Fig. 9-28). It is the first tributary of the superior vena cava, joining the latter as it passes ventral to the root of the lung. The other principal tributaries of the superior vena cava are the **brachiocephalic veins**, two large collecting trunks that receive blood from the head, neck, and upper limbs (Fig. 9-28).

Because the anatomy of the superior vena cava, pulmonary veins, and cardiac veins has already been discussed, only the following **veins of the thorax**, which contribute blood to the superior vena cava, will be described at this point:

- Azygos
- Brachiocephalic
  - Right brachiocephalic
  - Left brachiocephalic
  - Internal thoracic
  - Inferior thyroid
  - Superior intercostal
- Veins of the vertebral column

### Azygos Vein

The azygos vein in the adult is the vessel that persists from the fetal right posterior cardinal and right supracardinal veins (Figs. 9-1; 9-2). It usually commences opposite the first or second lumbar vertebra by a union of the ascending lumbar vein and the right subcostal vein, but it also may be joined at times by a tributary from the right renal vein, or a tributary from the inferior vena cava (Fig. 9-28). The azygos vein may enter the thorax through the aortic hiatus of the diaphragm, or it may pass into the thorax separately, through or behind the right crus of the diaphragm. It then ascends along the right side of the vertebral column to the fourth thoracic vertebra, where it arches anteriorly over the root of the right lung, and ends in the superior vena cava, just before that vessel pierces the pericardium. When the azygos vein traverses the aortic hiatus, it lies on the right side of the aorta, with the thoracic duct. In

the thorax it lies on the right posterior intercostal arteries, to the right of the aorta and thoracic duct, and is partly covered by pleura.

**TRIBUTARIES OF THE AZYGOS VEIN.** The azygos vein receives the following tributaries:

- Right superior intercostal vein
- Right fifth to eleventh posterior intercostal veins
- Right subcostal vein
- Hemiazygos vein
- Accessory hemiazygos vein
- Esophageal, mediastinal, and pericardial veins

A few imperfect valves are found in the azygos vein, but the valves of its tributaries are complete.

### RIGHT SUPERIOR INTERCOSTAL VEIN

Generally the right first intercostal vein drains into the right brachiocephalic vein or into one of its tributaries, such as the vertebral vein or the right subclavian vein. The second, third, and fourth right intercostal veins (and sometimes also the first) join to form a single trunk, called the **right superior intercostal vein**, which usually empties into the azygos vein as the latter arches over the hilum of the right lung. As will be described, the **left superior intercostal vein** drains into the left brachiocephalic vein.

### RIGHT FIFTH TO ELEVENTH POSTERIOR INTERCOSTAL VEINS

The right fifth to eleventh posterior intercostal veins drain directly into the azygos vein at their respective segmental levels (Fig. 9-28). The posterior intercostal veins are so named to distinguish them from the anterior intercostal veins, which are tributaries of the internal thoracic veins. Accompanying the intercostal arteries (one in each intercostal space), the intercostal veins lie along the upper border of the space, in a groove along the lower margin of the rib and in a position superior to the artery. Each vein receives a **dorsal tributary** from the muscles and cutaneous area of the back, and a **spinal tributary** that anastomoses with the plexuses of the vertebral column and spinal cord. The posterior intercostal veins also anastomose with the anterior veins of the internal thoracic, and with the lateral thoracic or thoracoepigastric veins.

**FIG. 9-28.** The venae cavae and azygos veins, with their tributaries. This pattern shows an expanded left superior intercostal vein, no accessory hemiazygos vein, and the left seventh posterior intercostal vein (not labeled) draining directly into the azygos vein.

**RIGHT SUBCOSTAL VEIN**

The right subcostal vein corresponds to the twelfth intercostal vein. It commences in the anterior abdominal wall on the right side and courses posteriorly around the trunk along the lower border of the twelfth rib. Dorsally, as it approaches the right lateral side of the body of the first lumbar vertebra, the right subcostal vein usually joins the right ascending lumbar vein to form the azygos vein. The **left subcostal vein** usually joins the hemiazygos vein.

**HEMIAZYGOS VEIN**

The hemiazygos vein is even more variable in its origin than the azygos vein, but most frequently it begins by the junction of the left subcostal vein and the ascending lumbar vein (Fig. 9-28). Either of these two vessels alone, however, may form the origin of the hemiazygos vein. It then enters the thorax through the left crus of the diaphragm with the left greater splanchnic nerve, but it may go through the aortic hiatus. Ascending on the left side of the vertebral column as high as the ninth thoracic vertebra, the hemiazygos vein passes horizontally across the vertebral column, dorsal to the aorta, esophagus, and thoracic duct, and ends in the azygos vein. It receives the caudal four or five left posterior intercostal veins, the subcostal vein of the left side, and some esophageal and mediastinal veins.

**ACCESSORY HEMIAZYGOS VEIN**

The accessory hemiazygos vein descends on the left side of the vertebral column. Typically, it receives the fourth to the eighth left posterior intercostal veins, and either crosses the body of the eighth thoracic vertebra to join the azygos vein or ends in the hemiazygos vein. It varies inversely in size with the left superior intercostal vein; when it is small, or altogether wanting, the left superior intercostal vein may extend as low as the fifth or sixth intercostal space.

**CLINICAL NOTE.** During obstruction of the inferior vena cava, the azygos and hemiazygos veins, as well as the vertebral veins, form important routes by which venous blood can be returned to the heart. These veins connect the superior and inferior venae cavae and communicate below with the common iliac veins via the ascending lumbar veins and with many of the tributaries of the inferior vena cava.

**ESOPHAGEAL, MEDIASTINAL AND PERICARDIAL VEINS**

**Esophageal veins**, draining the thoracic portion of the esophagus, open into the azygos and hemiazygos veins. These veins anastomose with upper esophageal vessels that drain into the left brachiocephalic vein, and with lower esophageal veins that also communicate with branches from the left gastric vein. Many small posterior **mediastinal veins** drain into the azygos and hemiazygos veins. In addition to draining into the internal thoracic and inferior phrenic veins, the **pericardial veins** communicate with the azygos and hemiazygos veins.

**BRONCHIAL VEINS**

There are usually two bronchial veins on each side, and these vessels return blood from the structures at the roots of the lungs. The **right bronchial veins** open into the azygos vein near its termination, while the **left bronchial veins** drain into the left superior intercostal or the accessory hemiazygos vein. A large quantity of the blood that is carried to the lungs through the bronchial arteries is returned to the left side of the heart through the pulmonary veins.

**Brachiocephalic Veins**

The brachiocephalic veins are two large trunks, right and left, located one on each side of the root of the neck (Fig. 9-28). They are formed by the junction of the internal jugular and subclavian veins of the corresponding side, and they terminate by uniting to form the superior vena cava. Because the superior vena cava is situated toward the right, the left brachiocephalic vein is longer than the right.

**RIGHT BRACHIOCEPHALIC VEIN**

The right brachiocephalic vein is a short vessel, about 2.5 cm in length, that begins behind the sternal end of the clavicle (Figs. 9-8; 9-28). It passes almost vertically downward and joins the left brachiocephalic vein to form the superior vena cava just below the cartilage of the first rib, close to the right border of the sternum. The right brachiocephalic vein lies anterior and to the right of the brachiocephalic artery; on its right side are the phrenic nerve and the pleura, which

are interposed between it and the apex of the lung. This vein, at its commencement, receives the right vertebral vein, and more caudally, the right internal thoracic and right inferior thyroid veins, and occasionally the vein from the first intercostal space.

#### LEFT BRACHIOCEPHALIC VEIN

The left brachiocephalic vein measures about 6 cm in length. From deep to the sternal end of the left clavicle, it courses obliquely downward and to the right, behind the upper half of the manubrium sterni (Fig. 9-28). At the sternal end of the first right costal cartilage, it unites with the right brachiocephalic vein to form the superior vena cava. It is separated from the manubrium sterni by the sternohyoid and sternothyroid muscles, the thymus or its remains, and some loose areolar tissue. Dorsal to the left brachiocephalic vein are the large brachiocephalic, left common carotid, and left subclavian arteries which arise from the aortic arch. Also behind the vein are the trachea and the left vagus and phrenic nerves. At times the brachiocephalic vein courses more superiorly and lies in the root of the neck at the level of the jugular notch.

**TRIBUTARIES OF THE BRACHIOCEPHALIC VEINS.** Both brachiocephalic veins receive as tributaries the vertebral, the internal thoracic, and the inferior thyroid veins. The left brachiocephalic vein also receives the left superior intercostal veins, and occasionally some thymic and pericardiac veins. The right brachiocephalic vein may receive the vein from the first intercostal space. Because the vertebral vein was described with the deep veins of the neck, the following vessels will be considered now also:

- Internal thoracic vein
- Inferior thyroid veins
- Superior intercostal veins

#### Internal Thoracic Veins

On each side the internal thoracic vein is the accompanying vein of the internal thoracic artery, and it receives tributaries corresponding to the branches of the artery (Fig. 9-28). Uniting to form a single trunk just below the manubriosternal joint, the internal thoracic vein ascends on the medial side of its artery and opens into the corresponding brachiocephalic vein. The **pericardiacophrenic vein**, which accompanys the pericardiacophrenic artery, usually flows into the internal thoracic vein.

**phrenic vein**, which accompanys the pericardiacophrenic artery, usually flows into the internal thoracic vein.

#### Inferior Thyroid Veins

Usually there are at least two, but frequently three or four, inferior thyroid veins. These arise in the venous plexus of the thyroid gland and communicate with the middle and superior thyroid veins (Fig. 9-28). At the level of the jugular notch, they form a plexus anterior to the trachea and deep to the sternothyroid muscles. From this plexus a left inferior thyroid vein descends and joins the left brachiocephalic vein, and a right vein passes obliquely downward and to the right across the brachiocephalic artery, and opens into the right brachiocephalic vein, close to its junction with the superior vena cava. Sometimes both inferior thyroid veins open by a common trunk, either into the left brachiocephalic vein or into the superior vena cava. The inferior thyroid veins drain the esophageal, tracheal, and inferior laryngeal veins, and are provided with valves at their terminations.

#### Superior Intercostal Veins

The right and left superior intercostal veins drain blood from the upper two or three intercostal spaces. The **right superior intercostal vein** passes downward and opens into the azygos vein. The **left superior intercostal vein** runs across the arch of the aorta and the origins of the left subclavian and left common carotid arteries, and opens into the left brachiocephalic vein (Fig. 9-28). It usually receives the left bronchial vein, and sometimes the left pericardiacophrenic vein. It has a prominent anastomosis with the accessory hemiazygos vein, and when the latter is missing, it drains all the upper left spaces.

#### Veins of the Vertebral Column

The veins that drain blood from the vertebral column, some adjacent musculature, and the meninges of the spinal cord form intricate plexuses that extend along the entire length of the column. These plexuses may be divided into two groups, external and internal, according to whether they are located outside or within the vertebral canal.

**FIG. 9-29.** Transverse section through the body of a thoracic vertebra, showing the vertebral venous plexuses. (After Netter.)

The plexuses of the two groups anastomose freely with each other and terminate in the intervertebral veins. The plexuses and veins of the vertebral system are:

- External vertebral venous plexuses
- Internal vertebral venous plexuses
- Basivertebral veins
- Intervertebral veins
- Veins of the spinal cord

#### EXTERNAL VERTEBRAL VENOUS PLEXUSES

The external vertebral venous plexuses are best developed in the cervical region and consist of anterior and posterior plexuses which anastomose freely with each other (Figs. 9-29; 9-30). The **anterior external plexuses** lie ventral to the bodies of the vertebrae, communicate with the basivertebral and intervertebral veins, and receive tributaries from the bodies of the vertebrae. The **posterior external plexuses** are placed partly on the dorsal surface of the vertebral arches and their processes, and partly between the deep dorsal muscles. In the cervical region the external vertebral plexuses

anastomose with the vertebral, occipital, and deep cervical veins. More inferiorly along the vertebral column, the external plexuses anastomose with the posterior intercostal veins of the thorax and with the lumbar veins of the posterior abdominal wall.

#### INTERNAL VERTEBRAL VENOUS PLEXUSES

The internal vertebral venous plexuses lie within the vertebral canal between the dura mater and the vertebrae, and receive tributaries from the bones and the spinal cord (Figs. 9-29; 9-30). They form a closer network than the external plexuses, and course mainly in a vertical direction, forming four longitudinal veins, two anterior and two posterior. The **anterior internal plexuses** consist of two large veins that lie along the posterior surface of the vertebral bodies and intervertebral discs on each side of the posterior longitudinal ligament. Under cover of this ligament, they are connected by transverse branches into which the basivertebral veins open. The two **posterior internal plexuses** are placed on each side of the midline

FIG. 9-30. Median sagittal section of three thoracic vertebrae, showing the vertebral venous plexuses.

ventral to the vertebral arches and ligamenta flava, and they anastomose by veins that pass through these ligaments with the posterior external plexuses. The anterior and posterior plexuses communicate freely with each other within the vertebral canal by a series of **venous rings**, one opposite each vertebra. Around the foramen magnum, the internal plexuses form an intricate network that opens into the vertebral veins and is connected above with the occipital and sigmoid sinuses, the basilar plexus, the condylar emissary vein, and the venous plexus in the hypoglossal canal.

#### BASIVERTEBRAL VEINS

The basivertebral veins emerge from the foramina on the dorsal surface of the vertebral bodies (Figs. 9-29; 9-30). They are thin-walled vessels contained in large, tortuous

channels in the cancellous tissue of the bodies of the vertebrae, similar in every respect to those found in the diploë of the cranial bones. They communicate through small openings anteriorly and laterally on the bodies of the vertebrae with the anterior external vertebral plexuses. They also converge posteriorly in the vertebral canal as single or doubled vessels that join the transverse branches uniting the anterior internal vertebral plexuses. The openings of the basivertebral veins are valved, and these vessels become greatly enlarged in advanced age.

#### INTERVERTEBRAL VEINS

The intervertebral veins accompany the spinal nerves through the intervertebral foramina (Figs. 9-29; 9-30). They receive blood from the veins of the spinal cord, drain the internal and external vertebral plexuses,

and flow into the vertebral, posterior intercostal, lumbar, and lateral sacral veins; their orifices are provided with valves.

#### VEINS OF THE SPINAL CORD

The veins of the spinal cord are situated in the pia mater, within which they form a tortuous venous plexus. They emerge chiefly from the median fissures of the cord and are largest in the lumbar region. In this plexus there are two **median longitudinal spinal veins**, one in front of the anterior median fissure and the other behind the posterior median sulcus of the cord. Additionally, there are two **anterolateral** and two **posterolateral longitudinal spinal veins** that course along the outer surface of the cord, deep to the dorsal and ventral roots. They drain into the intervertebral veins. Near the base of the skull they unite and form two or three small trunks. These communicate with the vertebral veins and then end in the inferior cerebellar veins or in the inferior petrosal sinuses.

**CLINICAL CONSIDERATIONS.** Batson (1940) discovered that the venous plexuses of the vertebral column constitute a system that parallels the caval system, and that if he injected a radiopaque substance into the dorsal vein of the penis in a cadaver, the substance found its way readily into the veins of the entire vertebral column, the skull, and the interior of the cranium. The material drained from the dorsal vein of the penis into the prostatic plexus and then followed communications with the veins of the sacrum, ilium, lumbar vertebrae, upper femur, and the venae cavae of the large femoral blood vessels, without traversing the main caval tributaries. Similarly, material injected into a small breast vein found its way into the veins of the clavicle, the intercostal veins, the head of the humerus, cervical vertebrae, and dural sinuses, without following the caval paths. Radiopaque material injected into the dorsal vein of the penis of an anesthetized monkey drained into the caval system when the animal was undisturbed, but if its abdomen was put under pressure, simulating the increased intra-abdominal pressure of coughing or straining, the material drained into the veins of the vertebrae.

There are certain instances in which metastases from pelvic organ tumors appear earlier in the pelvic bones, bodies of vertebrae, and central nervous system regions than in the lungs. According to Batson, this occurs during periods of increased abdominopelvic pressure (such as coughing, urination, and defecation), when considerable blood returns through the vertebral plexuses rather than through the inferior caval system.

## Inferior Vena Cava and its Tributaries

Draining into the inferior vena cava are most of the veins of the abdomen and pelvis and all of the veins of the lower extremities. Certain veins that receive blood from the lower anterior abdominal wall (inferior epigastric vein, superficial epigastric vein, external pudendal vein, and superficial circumflex iliac vein) drain inferiorly into the femoral or great saphenous vein, and thereby achieve the inferior vena cava. However, the superficial and deep veins, which drain the upper anterior abdominal and thoracic wall (superior epigastric vein, lateral thoracic vein), as well as the ascending lumbar veins that drain the posterior abdominal wall, flow into tributaries that drain into the superior vena cava.

#### INFERIOR VENA CAVA

The inferior vena cava returns blood from structures below the diaphragm to the right atrium of the heart (Fig. 9-31). It is formed by the junction of the two common iliac veins, anterior and slightly to the right of the body of the fifth lumbar vertebra. It ascends in front of the vertebral column, on the right side of the aorta, and when it reaches the liver, it lies in a groove on the dorsal surface of that organ. The inferior vena cava then perforates the diaphragm between the median and right portions of its central tendon. Subsequently, it inclines ventrally and medially for about 2.5 cm, and after piercing the fibrous pericardium, it becomes covered by a reflection of serous pericardium and opens into the right atrium near the level of the ninth thoracic vertebra. Anterior to its atrial orifice is a semilunar valve, the **valve of the inferior vena cava**, which is rudimentary in the adult but is large and exercises an important function in the fetus.

**RELATIONS OF THE INFERIOR VENA CAVA.** The **abdominal portion** of the inferior vena cava is overlaid *anteriorly* at its commencement by the right common iliac artery. It is crossed by the root of the mesentery and by the right ovarian or testicular artery. It is covered anteriorly by peritoneum in its ascent along the posterior abdominal wall as far as the horizontal (third) part of the duodenum. Losing its peritoneum, the inferior vena cava courses behind the

Fig. 9-31. The inferior vena cava and some of its tributaries.

horizontal part of the duodenum, as well as behind the head of the pancreas, the superior (first) part of the duodenum, the common bile duct, and the portal vein. Behind the hilum of the liver, it is again briefly covered by peritoneum until it achieves the posterior surface of the liver, which then partly overlaps and occasionally completely surrounds it. *Posterior* to the inferior vena cava are the bodies of the upper four lumbar vertebrae, the right psoas major muscle, the right crus of the diaphragm, the right inferior phrenic, suprarenal, renal, and lumbar arteries, right sympathetic trunk and right celiac ganglion, and the medial part of the right suprarenal gland. *On the right side*, the inferior vena cava is related to the right kidney and ureter (Fig. 9-31), while *on the left side* it is related to the aorta, right crus of the diaphragm, and the caudate lobe of the liver.

The **thoracic portion** is only about 2.5 cm in length and is situated partly inside and partly outside

the pericardial sac. The *extrapericardial part* of the inferior vena cava is separated from the right pleura and lung by the phrenic nerve and by a fibrous band, the **right phrenicopericardiac ligament**. This ligament, often feebly marked, is attached to the margin of the caval opening in the diaphragm and to the pericardium at the root of the right lung. The *intrapericardial part* of the inferior vena cava is short, and is covered by the serous layer of the pericardium.

**VARIATIONS IN THE INFERIOR VENA CAVA.** Because the inferior vena cava is formed by a rather complex series of developmental changes, it is not surprising that it has many structural anomalies. Cases have been reported in which there is an **absence of the hepatic or prerenal part of the inferior vena cava**. This results from the failure of the tributaries of the right subcardinal vein to join the veins of the liver between the fifth and sixth prenatal week. In these instances, the postrenal part of the inferior vena

cava joins the azygos or hemiazygos vein, which is then large. Thus, except for the hepatic veins, which pass directly to the right atrium, the superior vena cava receives all of the blood from the body before transmitting it to the right atrium.

More frequently, however, anomalies of the inferior vena cava involve the postrenal portion. These include **double inferior vena cava**, which results from persistence of the left subcardinal vein; **persistent left inferior vena cava**, with the absence of the right vessel; **preureteral inferior vena cava**, in which the right ureter passes behind and around the inferior vena cava to reach the bladder; and **persistent renal collar**, which is seen in cases of double venae cavae and involves two left renal veins interconnecting the venae cavae, one passing in front of and the other behind the aorta to form a ring (Gray and Skandalakis, 1972).

**COLLATERAL CIRCULATION.** The inferior vena cava below the renal arteries is sometimes ligated because of thrombosis. Channels of anastomosis for collateral circulation under these circumstances include the following: (1) the vertebral veins, (2) anastomoses between the lumbar veins of the inferior vena caval system and the ascending lumbar of the azygos system, (3) anastomoses between the superior, middle, and inferior rectal veins, (4) the thoracoepigastric vein, which connects the superficial inferior epigastric with the lateral thoracic vein, and (5) several anastomoses between vessels in the portal system of veins with vessels in the superior vena caval system, including left gastric-esophageal anastomosis and anastomosis between hepatic and diaphragmatic vessels along the bare area of the liver.

## VEINS OF THE ABDOMEN

The veins of the abdomen flow directly into the inferior vena cava, or achieve the inferior vena cava indirectly by draining into the portal system of veins that courses through the liver and out the hepatic veins to the inferior vena cava. Thus, the abdominal veins will be described under two headings: the parietal and posterior abdominal visceral veins, and the portal system of veins.

### *Parietal and Posterior Abdominal Visceral Veins*

The inferior vena cava receives blood from the two common iliac veins and from the following vessels:

- Lumbar
- Testicular
- Ovarian

- Renal
- Suprarenal
- Inferior phrenic
- Hepatic

## LUMBAR VEINS

The lumbar veins, four on each side, collect blood by dorsal tributaries from the muscles and integument of the lumbar region of the back, and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. Adjacent to the vertebral column, they receive veins from the vertebral plexuses, and then pass anteriorly around the sides of the bodies of the vertebrae, posterior to the psoas major muscle, and end in the dorsal part of the inferior vena cava. The left lumbar veins are longer than the right, and pass behind the aorta to reach the inferior vena cava. The lumbar veins are connected by a longitudinal vein, called the **ascending lumbar vein** (Fig. 9-28), which passes anterior to the transverse processes of the lumbar vertebrae. It is most frequently the origin of the azygos vein on the right side and of the hemiazygos vein on the left. These vessels provide anastomoses between the common iliac and ilio-lumbar veins of the inferior vena caval system, and between the azygos and hemiazygos veins of the superior vena caval system.

## TESTICULAR VEINS

The testicular veins emerge from the back of the testis, receive tributaries from the epididymis, and unite to form a convoluted mass of vessels called the **pampiniform plexus**, which constitutes the greater part of the spermatic cord (Fig. 9-32). The numerous vessels composing this plexus ascend along the cord, anterior to the ductus deferens. Just below the superficial inguinal ring, the vessels unite to form three or four veins that pass along the inguinal canal. Entering the abdomen through the deep inguinal ring, the veins coalesce to form two vessels that ascend on the psoas major. Under cover of the peritoneum and lying on either side of the testicular artery, the two veins unite to form a single testicular vein on each side. The **right testicular vein** opens into the inferior vena cava at an acute angle, while the **left testicular vein** flows into the left renal vein

FIG. 9-32. Testicular veins. (From Testut.)

at a right angle (Figs. 9-28; 9-31). The testicular veins are provided with valves. The left testicular vein passes behind the lower portion of the descending colon, and thus is exposed to pressure from the contents of that part of the bowel. The right testicular vein passes behind the distal part of the ileum and the horizontal or third part of the duodenum on its path to the inferior vena cava.

#### OVARIAN VEINS

The ovarian veins correspond to the testicular veins in the male. Each forms a plexus in the broad ligament near the ovary and uterine tube, which communicates freely with the uterovaginal plexus of veins. From the ovarian plexus in the broad ligament on each side emerge at least two vessels which unite to form a single vein. These terminate in a manner similar to that of the testicular veins, the **right ovarian vein** opening into the

inferior vena cava, and the **left ovarian vein** flowing into the left renal vein. Valves are usually found in these veins, especially near their junctures with the inferior vena cava and left renal vein. Like the uterine veins, the ovarian veins become much enlarged during pregnancy.

#### RENAL VEINS

The renal veins are large and pass anterior to the renal arteries (Figs. 9-28; 9-31). The **left renal vein** is longer (8.5 cm) than the right (3.5 cm), and it passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left testicular (or ovarian) and left inferior phrenic veins, and usually the left suprarenal vein. The left renal vein, due to the more superior position of the left kidney, opens into the inferior vena cava at a slightly higher level than the right renal vein. The short, thick **right renal vein** courses medially to the inferior vena

cava behind the descending (second) part of the duodenum. At times it sends a communicating tributary that helps to form the origin of the azygos vein.

### SUPRARENAL VEINS

Usually a single suprarenal vein emerges from each suprarenal gland, even though multiple arteries supply the glands (Fig. 9-28). The short **right suprarenal vein** passes transversely and opens directly into the inferior vena cava on its posterior aspect, while the longer **left suprarenal vein** courses inferomedially, behind the body of the pancreas, and opens into the left renal vein from above.

### INFERIOR PHRENIC VEINS

The inferior phrenic veins follow the course of the inferior phrenic arteries along the inferior surface of the diaphragm. The **right** vein ends in the inferior vena cava, while the **left** vein is represented by two branches, one of which opens into the left renal or suprarenal vein, and the other of which passes anterior to the esophageal hiatus in the diaphragm and empties into the inferior vena cava.

### HEPATIC VEINS

The hepatic veins commence in the substance of the liver by the coalescence of many **hepatic sinusoids** in the center of the hepatic lobules to form the central or **intra-lobular veins**. These latter vessels, as they leave the hepatic lobules, join one another to form the **sublobular veins**, which are the tributaries to the hepatic veins. The hepatic veins become arranged in two groups and emerge from the posterior surface of the liver to flow into the inferior vena cava. The **upper group** usually consists of three large veins: left, middle, and right. These converge toward the posterior surface of the liver and open into the inferior vena cava, which courses along its groove on the dorsal part of the liver (Figs. 9-28; 9-31). The veins of the **lower group** vary in number, are small, and come from the right and caudate lobes. The tributaries that form these hepatic veins run singly, are in direct contact with the hepatic tissue, and do not contain valves.

### Portal System of Veins

The **portal system** (Fig. 9-33) includes all of the veins that drain blood from the abdominal part of the digestive tube (except the lower part of the rectum) and from the spleen, pancreas, and gallbladder. From these, visceral blood is conveyed to the liver by the **portal vein**. In the liver this vein ramifies like an artery and ends in capillary-like vessels termed **sinusoids**, from which the blood is conveyed to the inferior vena cava by the **hepatic veins**. Thus, the blood in the portal system passes through two sets of minute vessels that allow an exchange of substances: (a) the capillaries of the digestive tube, spleen, pancreas, and gallbladder, and (b) the sinusoids of the liver. In the adult, the portal vein and its tributaries do not have valves, but in the fetus and for a short time after birth, valves can be demonstrated in the tributaries of the portal vein. As a rule these valves soon atrophy and disappear, but in some subjects their remnants can still be observed.

### PORTAL VEIN

The portal vein, about 8 cm in length, is formed at the level of the second lumbar vertebra, anterior to the inferior vena cava and behind the neck of the pancreas, by the junction of the superior mesenteric and splenic veins (Fig. 9-33). It passes behind the superior or first part of the duodenum and then ascends in the right border of the lesser omentum to the right portion of the porta hepatis. At this point it divides into a right and a left branch, each accompanying the corresponding branches of the hepatic artery into the substance of the liver. Within the lesser omentum, the portal vein lies posterior to the common bile duct and the hepatic artery, positioned in a plane between the two structures, with the duct oriented more to the right and the artery to the left. The portal vein is surrounded by the hepatic plexus of nerves, and is accompanied by numerous lymphatic vessels and some lymph nodes. The **right branch** of the portal vein courses almost transversely to the right at the porta hepatis, and generally receives the cystic vein from the gallbladder before entering the right lobe of the liver. The **left branch** is longer but of smaller caliber than the right. It ascends more vertically in the

porta hepatis, gives branches to the caudate and quadrate lobes, and then enters the left lobe of the liver. In its ascent, the left branch of the portal vein is joined anteriorly by a fibrous cord, the **ligamentum teres**, which represents the remains of the **obliterated umbilical vein**. The left branch is also united with the left hepatic vein, which then flows into the inferior vena cava by a second fibrous cord, the **ligamentum venosum**, which is the remnant of the fetal **ductus venosus**. The fetal umbilical vein is the principal channel by which oxygenated blood is returned to the fetus from the placenta. Blood is shunted to the inferior vena cava by means of the ductus venosus so that placental blood can reach the heart for distribution to the rest of the body.

**TRIBUTARIES OF THE PORTAL VEIN.** The portal vein forms at the junction of the splenic and superior mesenteric veins, but it also directly receives vessels that drain the lesser curvature of the stomach and the gallbladder. Additionally, communicating veins from the umbilical region of the anterior abdominal wall drain into the portal vein. Its tributaries include the following:

- Splenic (lienal)
- Superior mesenteric
- Left gastric
- Right gastric
- Prepyloric
- Cystic
- Paraumbilical

### Splenic Vein

The splenic (or lienal) vein commences as five or six tributaries that return blood from the spleen (Fig. 9-33). These unite to form a single vessel located medial to the hilum of the spleen; initially the vessel lies, with the splenic artery and the tail of the pancreas, between the leaves of the phrenicosplenic (lienorenal) ligament. The splenic vein then passes across the posterior abdominal wall, anterior to the upper third of the left kidney and behind the body of the pancreas, which it grooves and from which it receives many small veins. In its course it lies caudal to the lienal artery, and ends posterior to the neck of the pancreas by uniting at a right angle with the superior mesenteric vein to form the portal vein. The splenic vein is large, but is not tortuous like the artery.

**TRIBUTARIES OF THE SPLENIC VEIN.** The splenic vein receives the short gastric veins, the left gastroepiploic vein, the pancreatic veins, and the inferior mesenteric veins.

**Short Gastric Veins.** The short gastric veins, four or five in number, drain the fundus and left part of the greater curvature of the stomach (Fig. 9-33). These pass between the two layers of the gastrosplenic ligament and end in the splenic vein or in one of its large tributaries.

**Left Gastroepiploic Vein.** The left gastroepiploic vein receives tributaries from both the ventral and dorsal surfaces of the stomach and from the greater omentum (Fig. 9-33). It courses from right to left along the greater curvature of the stomach, with the left gastroepiploic artery, and usually flows into the splenic vein near its junction with the superior mesenteric vein.

**Pancreatic Veins.** The pancreatic veins consist of several small vessels that drain the body and tail of the pancreas and open into the trunk of the splenic vein.

**Inferior Mesenteric Vein.** The inferior mesenteric vein returns blood from the rectum and from the sigmoid and descending parts of the colon (Fig. 9-33). It begins in the rectum as the **superior rectal vein**, with its origin in the rectal plexus, and through this plexus it communicates with the middle and inferior rectal veins. The superior rectal vein then receives the **sigmoid veins** and leaves the lesser pelvis, accompanied by the superior rectal artery. After ascending across the common iliac vessels, the superior rectal vein receives the large **left colic vein**, which drains the left colic flexure and descending colon, and then continues its ascent as the inferior mesenteric vein. This vein lies to the left of its artery, and ascends under cover of the peritoneum, ventral to the left psoas major muscle. It then passes behind the body of the pancreas and opens into the splenic vein. Sometimes (10% of cases) the inferior mesenteric vein ends in the angle of union of the splenic and superior mesenteric veins, or it drains into the superior mesenteric vein.

### Superior Mesenteric Vein

The superior mesenteric vein returns blood from the small intestine, the cecum, and the ascending and transverse portions of

**FIG. 9-33.** The portal vein and its tributaries. Note that the pyloric end of the stomach and the transverse colon have been removed to reveal the underlying mesenteric veins.

the colon (Fig. 9-33). It begins in the right iliac fossa by the union of the veins that drain the terminal part of the ileum, the cecum, and the vermiform appendix, and it ascends between the two layers of the mesentery on the right side of the superior mesenteric artery. In its upward course, the superior mesenteric vein passes in front of the right ureter, the inferior vena cava, the horizontal part of the duodenum, and the uncinate process of the pancreas. Behind the neck of the pancreas it unites with the splenic vein to form the portal vein.

**TRIBUTARIES OF THE SUPERIOR MESENTERIC VEIN.** In addition to the tributaries that correspond to the branches of the superior mesenteric artery (the jejunal, ileal, ileocolic, right colic, and middle colic veins), the supe-

rior mesenteric vein is joined by the right gastroepiploic and the pancreaticoduodenal veins.

**Right Gastroepiploic Vein.** The right gastroepiploic vein receives tributaries from the greater omentum, parts of both ventral and dorsal surfaces of the stomach, and the anterior superior pancreaticoduodenal vein. It anastomoses with the left gastroepiploic vein and courses from left to right between the anterior two layers of the greater omentum, along the greater curvature of the stomach (Fig. 9-33).

**Pancreaticoduodenal Veins.** The superior and inferior pancreaticoduodenal veins correspond to their accompanying arteries and form venous arcades anterior and posterior to the head of the pancreas. The anterior

**superior** pancreaticoduodenal vein drains into the right gastroepiploic vein, while the **posterior superior** pancreaticoduodenal vein flows directly into the portal vein (Fig. 9-33). The **anterior** and **posterior inferior** usually drain singly or as a common trunk into the superior mesenteric vein or its first jejunal branch.

#### Left Gastric Vein

The left gastric vein frequently is called the coronary vein of the stomach, and it courses upward and from right to left along the lesser curvature (Fig. 9-33). It lies between the two layers of the lesser omentum and receives venous tributaries from both the anterior and posterior surfaces of the stomach. As the left gastric vein reaches the esophageal end of the stomach, it receives lower esophageal veins and then turns to the right and courses inferiorly, behind the peritoneum of the lesser omental sac (lesser omentum), and terminates in the portal vein.

#### Right Gastric Vein

The right gastric vein, at times called the pyloric vein, is a small vessel coursing between the two layers of the lesser omentum, along the lesser curvature of the stomach with the right gastric artery. It anastomoses with the left gastric vein midway along the lesser curvature, and it flows toward the right to empty most often into the portal vein. It may, however, terminate in the superior mesenteric vein or even in the right gastroepiploic vein. It is frequently joined by the **prepyloric vein**, which drains the stomach in the region of the pyloric canal.

#### Cystic Veins

The cystic veins consist of a number of small vessels that vary considerably in their drainage pattern of the gallbladder. As many as six or eight individual vessels flow directly along the attached (to the liver) anterior surface of the organ into the substance of the liver. The vessels draining the exposed serosal or posterior surface join at the neck of the gallbladder to form either single or double cystic veins (Fig. 9-33). These flow along the cystic duct and upward along the hepatic ducts and drain into the liver. Inferiorly, they anastomose with veins that drain

the common bile duct, and only rarely do the cystic veins drain directly into the portal vein or its main branches.

#### Paraumbilical Veins

The paraumbilical veins extend along the ligamentum teres of the liver and the median umbilical ligament. They are small vessels that establish an anastomosis between the veins of the anterior abdominal wall and the portal and internal iliac veins. The best marked of these small veins is one that commences at the umbilicus and courses dorsally and upward, between the layers of the falciform ligament along the surface or within the ligamentum teres, and ends in the left branch of the portal vein.

**COLLATERAL CIRCULATION BETWEEN THE PORTAL AND CAVAL VENOUS SYSTEMS.** Clinical conditions, such as cirrhosis of the liver, valvular heart disease, or the physical pressure of tumors, may obstruct or diminish the portal circulation through the liver. In these situations several collateral routes become available for the return of portal venous blood: (a) Tributaries of the left gastric veins of the portal system anastomose with tributaries of the lower esophageal veins that drain through the azygos and hemiazygos veins into the superior vena cava. (b) The superior rectal branches of the inferior mesenteric vein (portal system) anastomose with the middle rectal veins and the inferior rectal branches of the internal pudendal veins, which are tributaries of the internal iliac veins (inferior vena caval system). (c) In the umbilical region, small venous tributaries of the portal vein course along the ligamentum teres and the falciform ligament. These paraumbilical vessels anastomose with the superior epigastric and internal thoracic veins (superior vena cava) and with the inferior epigastric veins (inferior vena cava). Varicosities of these paraumbilical veins, radiating from the umbilicus, constitute a clinical condition called *caput medusae*. (d) Veins along the surface of the bare area of the liver (portal system) anastomose with small tributaries of the inferior phrenic veins that drain the inferior surface of the diaphragm (inferior vena cava). (e) Tributaries of intestinal veins that course in the roots of the mesenteries (portal system) anastomose with tributaries of retroperitoneal veins that drain the posterior abdominal wall.

#### VEINS OF THE PELVIS AND PERINEUM

Venous blood from the organs and much of the pelvic wall and from the muscles and external genitalia in the perineum drains into veins that join on each side to form the

**internal iliac vein.** This vessel joins its corresponding **external iliac vein** to form the **common iliac vein**. At the junction of the right and left common iliac veins, the inferior vena cava is formed (Figs. 9-28; 9-34).

### Common Iliac Veins

The common iliac veins, formed by the union of the internal and external iliac veins, commence anterior to the sacroiliac joint. Passing obliquely upward to the right side of the aorta and the body of the fifth lumbar vertebra, the two common iliac veins end by uniting with each other at an acute angle to form the inferior vena cava. The **right common iliac vein** is shorter than the left, nearly vertical in direction, and ascends dorsal and then lateral to its corresponding artery. The **left common iliac vein** is longer and more oblique in its course, and is situated at first on the medial side of its corresponding artery and later dorsal to the right common iliac artery. Each common iliac vein receives the **iliolumbar vein**, and sometimes the **lateral sacral veins**. Additionally, the left common iliac vein receives the **median sacral vein**. No valves are found in these veins.

**VARIATIONS OF THE COMMON ILIAC VEINS.** The left common iliac vein, instead of joining the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta and joins the right vein to form the inferior vena cava. In these bodies, the two common iliacs are connected by a small communicating branch at the site where usually they are united. This variation represents a persisting left posterior cardinal or supracardinal vein (Fig. 9-1, C and D).

### Iliolumbar Vein

The iliolumbar vein, coursing on each side with its corresponding artery, commences superiorly in the lower part of the posterior abdominal wall, where it anastomoses with the lower lumbar veins, and laterally in the iliac fossa just below the iliac crest (Fig. 9-34). Its lumbar tributary passes downward into the pelvis deep to the psoas major muscle, while its iliac tributary drains medially over the iliacus muscle. The two tributaries join to form the iliolumbar vein, which then courses inferiorly and medially and empties into the lateral aspect of the common iliac vein.

### Median Sacral Vein

The median sacral vein is formed by the junction of smaller vessels on each side that drain medially within the hollow on the anterior aspect of the sacrum. The vein ascends with its accompanying artery nearly in the midline and ends in the left common iliac vein, sometimes in the angle of junction of the two iliac veins.

### INTERNAL ILIAC VEIN

The internal iliac vein, formerly called the **hypogastric vein**, begins near the upper part of the greater sciatic foramen. It passes upward and backward in the pelvis, slightly medial to the corresponding artery. At the brim of the pelvis and anterior to the sacroiliac joint, the internal iliac vein joins the external iliac to form the common iliac vein (Fig. 9-34).

#### TRIBUTARIES OF THE INTERNAL ILIAC VEIN.

With the exception of the iliolumbar vein which usually joins the common iliac vein, the tributaries of the internal iliac vein correspond to the branches of the internal iliac artery. It receives the following:

- Superior gluteal
- Inferior gluteal
- Internal pudendal
- Obturator
- Lateral sacral
- Middle rectal
- Dorsal veins of penis and clitoris
- Vesical
- Uterine
- Vaginal

### Superior Gluteal Veins

The superior gluteal veins are *venae comitantes* of the superior gluteal artery. They receive tributaries corresponding with the branches of the artery from the gluteal structures, and enter the pelvis above the piriformis muscle through the greater sciatic foramen. Frequently the *venae comitantes* unite as a single vessel on each side before ending in the internal iliac vein.

### Inferior Gluteal Veins

The inferior gluteal veins are *venae comitantes* of the inferior gluteal artery. They begin on the proximal part of the posterior thigh, where they anastomose with the me-

the ureter and the internal iliac artery, and ends in the internal iliac vein.

### Lateral Sacral Veins

The lateral sacral veins accompany the lateral sacral arteries on the anterior surface of the sacrum and open into the internal iliac vein. As the lateral sacral veins ascend along the posterolateral pelvic wall, they are joined by vessels that emerge through the pelvic (anterior) sacral foramina. The veins of the two sides anastomose and join in the formation of the sacral venous plexus.

### Middle Rectal Vein

The middle rectal vein originates in the rectal plexus and receives tributaries from the bladder, prostate, and seminal vesicle (Fig. 9-34). It courses laterally on the pelvic surface of the levator ani muscle and ends in the internal iliac vein.

**RECTAL VENOUS PLEXUS.** The rectal venous plexus surrounds the rectum and communicates anteriorly with the vesical plexus in the male or the uterovaginal plexus in the female (Fig. 9-34). It consists of two parts, an **internal rectal plexus** in the submucosa, and an **external rectal plexus** outside the muscular coat. The internal plexus presents a series of dilated pouches that are connected by transverse vessels and are arranged in a circle around the tubular rectum, immediately above the anal orifice. The lower part of the external plexus is drained by the **inferior rectal veins** into the internal pudendal vein; the middle part drains into the **middle rectal vein** which joins the internal iliac vein; and the upper part is drained by the **superior rectal vein** which forms the commencement of the inferior mesenteric vein, a tributary of the portal vein. A free communication between the portal and systemic venous systems is established through the rectal plexus.

**CLINICAL CORRELATION.** The veins that form the internal rectal plexus are contained in very loose connective tissue; thus they get less support from surrounding structures than do most other veins, and are less capable of resisting increased blood pressure. Frequently they become dilated and varicose, forming internal hemorrhoids or piles. Varicosities of the external rectal veins also cause painful external hemorrhoids. Enlargement of these veins can occur when the portal vein is obstructed or in childbearing women.

### Dorsal Veins of the Penis and Clitoris

On the dorsum of the penis are located both superficial and deep veins (Fig. 9-35). The **superficial dorsal vein** drains the prepuce and skin of the penis. It courses proximally in the subcutaneous tissue, inclines to the right or left, and opens into the corresponding superficial external pudendal vein, a tributary of the great saphenous vein. The **deep dorsal vein** lies beneath the deep fascia of the penis, but superficial to the tunica albuginea of the corpora cavernosa. It receives blood from the glans penis and from the corpora cavernosa by way of the deep veins of the penis. It courses proximally in the midline between the two dorsal arteries. Near the root of the penis it enters the pelvis by passing between the two parts of the suspensory ligament and then through an aperture just below the arcuate pubic ligament of the symphysis pubis. The deep dorsal vein then divides into two branches that enter the **prostatic plexus**, one on each side. The deep dorsal vein also anastomoses with the internal pudendal vein, distal to the symphysis pubis.

The **dorsal vein of the clitoris** drains the erectile tissue of that organ and courses backward into the pelvis in a manner similar to that in the male. It terminates in the venous plexus around the bladder, the **vesical venous plexus**. In contrast, the venous blood from the vestibular bulb and the other structures in the urogenital region of the female, along with the tissue within the ischiorectal fossa and surrounding the anus, drains backward and laterally into the internal pudendal veins. Thus, venous blood from most of the female perineum enters the pelvis along routes comparable to those in the male (Fig. 9-36).

**FIG. 9-35.** The penis in transverse section, showing the blood vessels.

**Fig. 9-36.** The veins of the anal and urogenital regions of the female perineum.

**PROSTATIC VENOUS PLEXUS.** The prostatic venous plexus lies behind the arcuate pubic ligament and the symphysis pubis, and in front of the bladder and prostate. Its chief tributary is the deep dorsal vein of the penis, but it also receives tributaries from the bladder and prostate. It anastomoses with the vesical plexus, the internal pudendal vein, and the vertebral veins, and drains into the vesical and internal iliac veins. The prostatic plexus lies partly in the fascial sheath of the prostate and partly between the sheath and the prostatic capsule.

#### Vesical Veins

The vesical veins envelop the caudal part of the bladder and the base of the prostate. They form the **vesical venous plexus** and anastomose with the prostatic plexus in the male or with the uterine and vaginal plexuses in the female. The vesical venous plexus drains by means of several vesical veins that frequently unite into one or two vessels on each side before entering the internal iliac vein.

#### Uterine Veins

A complex network of uterine veins courses along the sides of the uterus between the two layers of the broad ligament (Fig. 9-37). The veins form the **uterine venous plexuses** and anastomose with the ovarian and vaginal plexuses. From the inferior part of the uterine plexuses, at the level of the external orifice of the cervix, arises a pair of uterine veins on each side. These course laterally and posteriorly and open into the corresponding internal iliac vein.

#### Vaginal Veins

The venous drainage of the vagina occurs by means of **vaginal plexuses** along the sides of the vagina (Fig. 9-37). These are in continuity with the uterine plexuses and they also communicate with the vesical and rectal plexuses. The vaginal plexuses are drained by at least one, and at times two vaginal veins on each side that flow into the internal iliac veins either directly or through connections with the internal pudendal veins.

**FIG. 9-37.** The blood vessels of the female pelvis, showing the chief source of blood supply to the uterus and vagina. (From Eycleshymer and Jones.)

#### EXTERNAL ILIAC VEIN

The external iliac vein is the upward continuation of the femoral vein and therefore receives blood from the lower limb (Figs. 9-28; 9-34). It also drains the lower part of the anterior abdominal wall. The femoral vein becomes the external iliac vein at the level

of the inguinal ligament. Passing superiorly along the brim of the lesser pelvis, the external iliac vein ends opposite the sacroiliac joint by uniting with the internal iliac vein to form the common iliac vein. *On the right side*, it lies at first medial to the external iliac artery, but as it passes upward it gradually inclines behind the artery. *On the left side*, it

lies altogether on the medial side of the artery. It frequently contains one, sometimes two, valves.

#### TRIBUTARIES OF THE EXTERNAL ILIAC VEIN.

As it ascends, the external iliac vein receives the following veins:

- Inferior epigastric
- Deep circumflex iliac
- Pubic

#### Inferior Epigastric Vein

The inferior epigastric vein is formed by the union of the venae comitantes of the inferior epigastric artery. At their source superiorly, the venae comitantes anastomose with the superior epigastric vein. The inferior epigastric vein joins the external iliac vein about 1.25 cm above the inguinal ligament.

#### Deep Circumflex Iliac Vein

The deep circumflex iliac vein is formed by the union of the venae comitantes of the deep circumflex iliac artery, and joins the external iliac vein about 2 cm above the inguinal ligament.

#### Pubic Vein

The pubic vein interconnects the obturator vein in the obturator foramen and the external iliac vein. It ascends on the inner aspect of the pubis and accompanies the pubic branch of the obturator artery. In about 33% of cases, it is enlarged, functionally taking the place of the obturator vein. In these instances it becomes a dangerous vessel when operations are made in the region of the femoral ring.

### VEINS OF THE LOWER LIMB

The veins of the lower limb are subdivided into superficial and deep sets in a manner similar to those of the upper limb. The **superficial veins** course in the superficial fascia just beneath the skin, while the **deep veins** accompany the arteries. Both sets of veins are provided with valves, which are more numerous in the deep veins than in the superficial. A greater number of valves is

also found in the veins of the lower limb than in veins of the upper limb.

#### Superficial Veins of the Lower Limb

The superficial veins of the lower limb are the **great** and **small saphenous veins**, their tributaries, and the **superficial veins of the foot**.

#### GREAT SAPHENOUS VEIN

The great saphenous vein is the longest vein in the body, beginning in the superficial vein that courses along the dorsomedial margin of the foot. It terminates in the femoral vein about 3 cm below the inguinal ligament (Fig. 9-38). It ascends anterior to the tibial malleolus and along the medial side of the leg together with the saphenous nerve. Passing upward behind the medial condyles of the tibia and femur, it then ascends along the medial side of the anterior thigh to a point about 3 cm below the inguinal ligament, where it dips through the **saphenous hiatus** (fossa ovalis), penetrates the lower end of the femoral sheath, and opens into the femoral vein.

**CLINICAL CORRELATION.** The great saphenous vein contains between 10 and 20 valves. These are more numerous in the leg than in the thigh. Frequently this vein and its branches become dilated and then varicose. This results when valves that normally prevent the flow of venous blood from the long deep veins to those more superficial in the lower limb become incompetent. Dangerous thrombi may develop, especially from the portion of the great saphenous vein which extends from the midregion of the calf to the upper third of the thigh.

#### TRIBUTARIES OF THE GREAT SAPHENOUS VEIN.

At the ankle, the great saphenous vein receives tributaries from the sole of the foot by way of the medial marginal vein. In the leg, it anastomoses freely with the small saphenous vein, communicates with the anterior and posterior tibial veins from deeper in the leg, and receives many cutaneous veins. In the thigh, it anastomoses with the femoral vein and receives numerous tributaries. Those from the medial and posterior parts of the thigh frequently unite to form a large **accessory saphenous vein** that joins the main vein at a variable level. Near the saphenous hiatus it is joined by the **superficial external**

FIG. 9-38. The great saphenous vein and its tributaries.

pudendal, superficial circumflex iliac, and superficial epigastric veins (Fig. 9-38). Additionally, through the superficial epigastric vein it forms an anastomosis with veins of the upper limb by means of the **thoracoepigastric vein**. Of these tributaries the following will be described further:

Accessory saphenous  
Superficial external pudendal  
Superficial circumflex iliac  
Superficial epigastric  
Thoracoepigastric

#### Accessory Saphenous Vein

The accessory saphenous vein is the name frequently given to the superficial vein that arises along the posteromedial border of the thigh. It ascends around the medial aspect of the thigh, receiving tributaries primarily from the posterior surface, and joins the saphenous vein on its medial aspect. At times this vessel is called the **medial accessory saphenous vein**, to differentiate it from the **lateral accessory saphenous vein**, which arises anteriorly just above the knee (Fig. 9-38). Receiving tributaries from the lateral and anterior surfaces of the thigh, the lateral accessory saphenous vein ascends on the front of the thigh and opens into the saphenous vein on its lateral aspect (Daseler et al., 1946).

#### Superficial External Pudendal Vein

The superficial external pudendal vein forms from tributaries that laterally drain the superficial fascia from the upper medial thigh, the lower medial inguinal region, and the scrotum (or labia majora) (Fig. 9-38). It usually (90% of cases) opens into the great saphenous vein, but at times (10%) flows into the medial accessory saphenous vein.

#### Superficial Circumflex Iliac Vein

The superficial circumflex iliac vein forms from tributaries that drain the superficial fascia over the uppermost lateral surface of the anterior thigh, extending even from the anterior abdominal wall above the lateral part of the inguinal ligament (Fig. 9-38). The vein descends medially in an oblique course and opens directly into the great saphenous vein (60% of cases) or into the lateral accessory saphenous vein (40%).

#### Superficial Epigastric Vein

The superficial epigastric vein arises from tributaries that drain the superficial fascia over a rather wide region of the lower anterior abdominal wall (Fig. 9-38). These tribu-

taries descend directly from the pubic region or obliquely from the more lateral inguinal region, and become a single vessel that opens into the lateral (80% of cases) or medial (20%) aspect of the great saphenous vein or into the corresponding accessory saphenous vein. The superficial epigastric vein anastomoses by way of the **thoracoepigastric vein** with vessels draining superiorly over the thoracic wall.

**THORACOEPIGASTRIC VEIN.** The thoracoepigastric vein is a longitudinally oriented vessel whose tributaries form an anastomo-

sis over the anterior abdominal and thoracic walls (Fig. 9-39). It connects venous channels that drain into the axillary vein, usually by means of the lateral thoracic vein, with others that drain into the superficial epigastric and superficial circumflex iliac veins, which flow into the great saphenous-femoral venous complex. Normally the vein is a relatively small vessel that simply contributes to the drainage of the superficial fascia. However, the thoracoepigastric vein provides an important collateral channel in clinical conditions that obstruct either the inferior vena

**FIG. 9-39.** The thoracoepigastric vein and other superficial veins of the anterior thoracic wall.

cava or the portal vein. Under these circumstances this vein can become greatly enlarged and tortuous.

### SMALL SAPHENOUS VEIN

The small saphenous vein begins behind the lateral malleolus as a continuation of the marginal vein that courses along the dorso-lateral aspect of the foot. At first it ascends along the lateral border of the calcaneal tendon and then crosses this tendon to reach the middle of the back of the leg. Running directly upward, it perforates the deep fascia in the distal part of the popliteal fossa, and ends in the popliteal vein between the two heads of the gastrocnemius muscle (Fig. 9-40). It anastomoses with the deep veins on the dorsum of the foot, and receives numerous large tributaries from the superficial fascia on the back of the leg. Before the small

FIG. 9-40. The small saphenous vein.

saphenous vein pierces the deep fascia, it joins a vessel that courses superiorly and anteriorly to anastomose with the great saphenous vein. In its ascent, the small saphenous vein possesses from 9 to 12 valves, one of which is always found near its termination in the popliteal vein. In the distal third of the leg the small saphenous vein is accompanied by the sural nerve, and in the proximal two-thirds by the medial sural cutaneous nerve.

### SUPERFICIAL VEINS OF THE FOOT

On the dorsum of the foot, the **dorsal digital veins** communicate with the plantar digital veins in the clefts between the toes. The adjacent dorsal digital veins join to form the **dorsal metatarsal veins**. These latter vessels unite across the distal ends of the metatarsal bones in a **dorsal venous arch** (Fig. 9-38). Proximal to this arch is an irregular venous network that receives tributaries from the deep veins. This network is joined at the sides of the foot by **medial and lateral marginal veins**, which are formed mainly by the union of branches from the superficial parts of the sole of the foot.

On the sole of the foot, the superficial veins form a **plantar cutaneous venous arch** that extends across the roots of the toes and opens at the sides of the foot into the medial and lateral marginal veins. Proximal to this arch is a **plantar cutaneous venous network** that is especially dense in the fat beneath the heel. This network communicates with the cutaneous venous arch and with the deep veins, but drains chiefly into the medial and lateral marginal veins.

### Deep Veins of the Lower Limb

The deep veins and their tributaries in the lower limb accompany the arteries and their branches, and they possess numerous valves. Sequentially they include:

- Deep veins of the foot
- Deep veins of the leg
- Popliteal vein
- Deep veins of the thigh

### DEEP VEINS OF THE FOOT

The **plantar digital veins** arise from plexuses on the plantar surfaces of the digits, and after sending communicating vessels to join

the dorsal digital veins, they unite to form four **plantar metatarsal veins**. These course proximally in the metatarsal spaces and anastomose by means of perforating veins with the veins on the dorsum of the foot. The plantar metatarsal veins unite to form the **deep plantar venous arch**, which accompanies the plantar arterial arch across the plantar aspect of the foot between the oblique part of the adductor hallucis muscle and the interossei muscles. From the deep plantar venous arch, the **medial** and **lateral plantar veins** run proximally near their corresponding arteries. They communicate by anastomosing vessels with the great and small saphenous veins on the two sides of the foot. The medial and lateral plantar veins then unite to form the **posterior tibial veins** behind the medial malleolus.

#### DEEP VEINS OF THE LEG

The deep veins of the leg ascend with their accompanying arteries in both the anterior and posterior compartments. The principal deep veins include:

- Posterior tibial
- Peroneal
- Anterior tibial

#### Posterior Tibial Veins

The posterior tibial veins accompany the posterior tibial artery. Paired as *venae comitantes* in the lower leg, the vessels at times join to form a single vein, which with its artery ascends in the fascial plane between the superficial and deep muscles of the posterior compartment. The posterior tibial veins drain blood from these posterior compartment muscles and also receive communicating vessels from the more superficial veins. Two-thirds of the way up the leg, the posterior tibial veins receive the **peroneal veins** (Fig. 9-41).

**PERONEAL VEINS.** The peroneal veins ascend obliquely in the same plane as the posterior tibial veins from the lateral aspect of the leg. They accompany the peroneal artery and open into the posterior tibial veins distal to the popliteal fossa, just below the lower border of the popliteus muscle (Fig. 9-41). The peroneal veins drain the lateral compartment muscles and also muscles of the posterior compartment.

**FIG. 9-41.** The popliteal vein and the junction of the peroneal and posterior tibial veins.

#### Anterior Tibial Veins

The anterior tibial veins accompany the anterior tibial artery and deep peroneal nerve, and they are the upward continuation of the *venae comitantes* of the dorsalis pedis artery. Ascending above the ankle joint in the lower leg between the tibialis anterior and extensor hallucis longus muscles, the anterior tibial veins course deeply on the interosseous membrane. In the upper leg the neurovascular bundle lies between the tibialis anterior and the extensor digitorum longus. The veins leave the anterior leg by passing between the tibia and fibula through the upper part of the interosseous membrane. They unite with the posterior tibial veins just below the popliteal fossa in the posterior compartment to form the **popliteal vein**.

#### POPLITEAL VEIN

The popliteal vein is formed by the junction of the anterior and posterior tibial veins at the distal border of the popliteus muscle.

It ascends through the popliteal fossa to the aperture in the adductor magnus muscle, called the adductor hiatus, where it becomes the femoral vein in the adductor canal. In the lower part of its course within the popliteal fossa, it is placed medial to the popliteal artery (Fig. 9-41); between the heads of the gastrocnemius muscle, it lies superficial to that vessel; above the knee joint, it remains superficial to the popliteal artery but courses along its lateral side. The popliteal vein receives tributaries corresponding to the branches of the popliteal artery, as well as the small saphenous vein, and in its course it usually contains four valves.

### DEEP VEINS OF THE THIGH

The deep veins of the thigh accompany the deep arteries. The principal deep vein is the **femoral vein**, and into this flow the **deep femoral vein**, the **saphenous vein**, and the **medial and lateral femoral circumflex veins**. Additionally, the **perforating veins** which drain the posterior structures of the thigh are large tributaries of the deep femoral vein.

#### Femoral Vein

The femoral vein, accompanying the femoral artery, ascends from the superior end of the popliteal fossa through the adductor canal, lateral to and somewhat behind the artery. Proximal to the adductor canal in the lower part of the femoral triangle, the femoral vein lies behind the artery and as it ascends, it gradually crosses to the medial side of the artery. At the level of the inguinal ligament it occupies the medial compartment of the femoral sheath, and the femoral vein becomes the external iliac vein above the ligament. The femoral vein receives numerous muscular tributaries, and about 4 cm or more below the inguinal ligament, it is joined on its posterior aspect by the deep femoral vein and somewhat higher on its anterior aspect by the saphenous vein. Also the medial and lateral femoral circumflex veins may open either into the femoral vein or into the deep femoral vein. There are usually three or four valves in the femoral vein; one is generally found (in 90% of cases) just below the entrance of the deep femoral vein (Basmajian, 1952).

**DEEP FEMORAL VEIN.** The deep femoral vein is formed by the junction of three or

four **perforating veins** that correspond to the perforating branches of the deep femoral artery. Through the perforating veins, anastomoses are established by the femoral vein with the inferior gluteal vein above and with the popliteal vein below. The perforating veins return blood from muscles in all three compartments of the thigh, as well as from the femur.

**MEDIAL AND LATERAL FEMORAL CIRCUMFLEX VEINS.** The medial and lateral femoral circumflex veins do not terminate in a pattern consistent with the origin of the corresponding arteries. In 86% of cases studied, the two femoral circumflex veins terminate in the femoral vein, whereas in 2% both veins terminate in the deep femoral vein. In the remaining 12% either the medial or the lateral femoral circumflex vein joins the femoral vein, while the other joins the deep femoral vein (Baird and Cope, 1933).

## Histology of the Blood Vessels

### ARTERIES

The arterial system consists of an elaborate system of tubular structures that conducts blood away from the heart. All arteries are composed of three coats: an inner coat called the **tunica intima**, an intermediate coat, the **tunica media**, and an external coat, the **tunica adventitia** (Fig. 9-42). The composition and relative thickness of these coats differ in arteries of different size; however, in all of these the functional cell type of the tunica intima is the endothelial cell, that of the tunica media is the smooth muscle cell, while the principal cell type of the tunica adventitia is connective tissue.

**TUNICA INTIMA.** The tunica intima, or innermost coat, consists of a thin lining of **endothelial cells** that is longitudinally oriented and continuous with the endothelium of capillaries on the one hand and with the endocardium of the heart on the other. The endothelium is a single layer of simple squamous or plate-like cells, polygonal, oval, or fusiform in shape, with rounded oval or flattened nuclei. Although the outlines of the cells can be brought out by treatment with silver nitrate, studies in recent years utilizing the electron microscope have shown that

endothelial cells are closely apposed, being separated by only about 200 Å, and contain little or no intercellular cement at their junctions. The endothelial cells rest on a **basal lamina**, and in arteries larger than arteriolar capillaries, delicate strands of connective tissue form a **subendothelial layer** that intervenes between the endothelium and the **internal elastic membrane**. The latter is easily identified in muscular arteries. It consists of a network of elastic fibers arranged more or less longitudinally, leaving elongated apertures or perforations that give it a fenestrated appearance. Fine cytoplasmic processes on the basal surface of the endothelial cells project through the fenestrations of the internal elastic membrane to achieve contact with the overlying smooth muscle cells of the tunica media. The internal elastic membrane forms the chief thickness of the tunica intima, and it is thrown into folds when arteries are fixed histologically. In microscopic

cross sections the internal elastic membrane appears as a wavy line, glassy and almost unstained when using routine histological techniques such as hematoxylin and eosin; however, it stains heavily with special substances such as orcein, which characteristically reacts with elastic tissue.

**TUNICA MEDIA.** The tunica media, or middle coat, is principally composed of thin, cylindrical smooth muscle cells and elastic tissue, and it accounts for the bulk of the wall of most arteries. The smooth muscle cells are disposed in circular layers around the vessel, and the thickness of the tunica media, as well as its composition, varies with the size of the vessel. The smooth muscle cells are held together by an abundant amount of intercellular glycoprotein, which contains collagen fibrils and reticular and elastic fibers. The intercellular material is probably formed by the smooth muscle cells themselves, because virtually no other cells

**Fig. 9-42.** Cross section of parts of the walls of adjacent medium-sized artery and vein. Artery, lower left; vein, upper right.

are found in the tunica media. The external margin of the tunica media frequently is marked by a prominent layer of elastic tissue called the **external elastic membrane**.

**TUNICA ADVENTITIA.** The tunica adventitia, or outer coat, consists of areolar connective tissue that contains fibroblasts within a fine meshwork of elastic fibers and bundles of collagen. As described previously, the elastic tissue is more abundant adjacent to the tunica media, where it is called the external elastic membrane. The tunica adventitia varies in thickness in different types of arteries, but usually it is not as thick as the tunica media.

The tunica adventitia contains the **vasa vasorum**, which are the arteries and veins that supply the vessel walls. It also contains fine lymphatic vessels, as well as the nerve fibers that supply the arteries. The latter appear to terminate near or within the external elastic membrane.

As arteries extend distally, there is a gradual transition in their size. Certain features characterize arteries of different sizes.

### Large Elastic Arteries

Large elastic arteries such as the aorta and its major branches, as well as the pulmonary trunk and its two principal branches, con-

duct blood from the heart to the smaller distributing arteries (Fig. 9-43). They have a thick **tunica intima**, and although the **endothelium** is still only a single layer in thickness, the **subendothelial layer** contains considerable connective tissue that is composed of bundles of collagen and some smooth muscle cells along with occasional macrophages. Surrounding the subendothelial connective tissue is a **fenestrated elastic tissue layer**, which in smaller vessels is considered to be the internal elastic membrane. In large arteries, however, it is difficult to determine the external boundary between the tunica intima and the internal border of the tunica media, because the **tunica media** contains many concentric layers of fenestrated elastic tissue (Fig. 9-43). There may be 50 or more elastic laminae in the tunica media, and interspersed between these elastic fibers are smooth muscle cells, collagenous fibers, and extracellular ground substance (Fig. 9-44).

The **tunica adventitia** of large arteries is thin relative to the tunica media and the line of transition may not be easily apparent. Characteristically, the connective tissue of the external coat is more fibrous in nature and contains more collagen and less elastic tissue. The tunica adventitia of large vessels also contains numerous small vessels

**FIG. 9-43.** Photomicrograph of a section of the wall of the aorta, stained for elastic fibers. Note the relative widths of the three layers. 24  $\times$ .

**FIG. 9-44.** Photomicrograph of the tunica media of the human aorta showing many lamellae of elastic fibers, which characterize the microscopic anatomy of that coat in the walls of large elastic arteries. 144  $\times$ .

and nerves, the *vasa vasorum* and *nervi vasorum*, and its external layers gradually merge with the surrounding connective tissue.

### **Medium-Sized Muscular Arteries**

The medium-sized arteries include most of the named arteries that distribute blood to the different organs and parts of the body. The **tunica intima** is formed by a single layer of endothelium resting on a basal lamina. Deep to this is a thin subendothelial layer that lies adjacent to a well-defined fenestrated internal elastic lamina. The muscular coat, or **tunica media**, is especially well developed and the physiology of the smooth muscle cells is under the influence of neuro-humors liberated by the vasomotor nerves. This mechanism controls the flow of blood by altering the diameter of the lumen of these arteries. In the somewhat smaller arteries the tunica media is almost entirely muscular, but in larger ones more and more elastic tissue is interposed with the smooth muscle cells (Fig. 9-45). The thickness of the **tunica adventitia** is variable. In arteries located in well-protected sites such as those in the abdominal or cranial cavities, it is relatively thin, but it is much thicker in exposed regions such as the limbs. The bundles of

nerve fibers are numerous in the tunica adventitia of many muscular arteries, and on some arteries supplying the abdominal organs they are so profuse that they form extensive plexuses that coat the vessels almost completely.

### **Small Arteries and Arterioles**

As the named muscular arteries are distributed peripherally, they branch into smaller muscular arteries; these divide into **muscular arterioles**, which then branch into **terminal arterioles** less than 50  $\mu\text{m}$  in diameter (Figs. 9-46; 9-47). The **tunica intima** of arterioles consists of a layer of flattened, elongated endothelial cells resting on a basal lamina. In cross sections of larger arterioles, a corrugated internal elastic membrane surrounds the endothelium; however in arterioles of small diameter, less elastic tissue is seen and this membrane is incomplete. In the smallest terminal arterioles, the elastic tissue disappears completely (Fig. 9-47).

The **tunica media** of arterioles consists of smooth muscle cells, and its thickness varies directly with the diameter of the vessels. In the larger arterioles, perhaps three or more layers of smooth muscle cells surround the endothelium in a circumferential pattern, whereas in the terminal arterioles the tunica

**FIG. 9-45.** Photomicrographs of intercostal artery (A, C) and vein (B, D). A and B are stained with hematoxylin and eosin, while C and D are stained for elastic fibers. Arrows mark the boundary between the tunica media (above) and tunica adventitia (below) in each photomicrograph.  $130\times$ . (From Windle, W. F., *Textbook of Histology*, 4th ed., McGraw-Hill, New York, 1969.)

media consists of only a single layer of smooth muscle. The **tunica adventitia** of larger arterioles consists of loose connective tissue with some collagenous and elastic fibers and fibroblasts, but this outer coat becomes less well defined and greatly reduced in the smallest arterioles (Fig. 9-47).

### Capillaries

From the smallest arteriolar vessels, fine networks of endothelium-lined tubes permeate most tissues and organs (Fig. 9-48). These minute tubes are the capillaries and their networks form the functional and morpho-

**Fig. 9-46.** Small artery and vein, pia mater of sheep. 250  $\times$ . Surface view above the interrupted line; longitudinal section below. Artery in red; vein in blue.

logic connections between the arterial and venous systems. Frequently and closely associated with the outer surface of endothelial cells are macrophages or mesenchymal perivascular cells called **pericytes**. Although there is some variation in their size, the average diameter of capillaries is about  $8\text{ }\mu\text{m}$ , roughly equivalent to that of a red blood corpuscle (Fig. 9-48). Functionally, capillaries carry nutrient substances to tissues and organs and take away the metabolic products of cells. These processes require the transfer of substances across the capillary wall, utilizing the permeable nature of the endothelial lining. The anatomical basis of capillary permeability and the sites through which substances pass across the endothelial lining has been a subject of intensive study both physiologically and with the electron microscope. On morphological grounds, two types of capillaries have been described, the **continuous** and the **fenestrated**.

**CONTINUOUS CAPILLARIES.** Continuous capillaries are usually seen in muscle, skin, and connective tissue and in the brain and spinal cord. Along both the luminal and outer surfaces of the endothelial cells in this type of capillary are found numerous pinocytotic vesicular invaginations, called **caveolae**, which measure between 500 and  $700\text{ }\text{\AA}$  (Fig. 9-49). It is theorized that these vesicles may be sites for the entrapment of large molecules, and that the vesicles then pinch off and traverse the endothelial cell

cytoplasm to the opposite surface, where they fuse with the membrane again and their contents are discharged outside the endothelial cell. Continuous capillaries have walls of endothelial cells whose basal laminae are continuous and whose intercellular junctions are of the occludens type. These junctional complexes have intercellular spaces that measure only about 150 to  $200\text{ }\text{\AA}$ ; these narrow spaces are believed to be wide enough to allow water and simple solutions to pass through them, but not larger molecules such as proteins (Fig. 9-50).

**FENESTRATED CAPILLARIES.** Fenestrated capillaries are found in the glomeruli of the kidney, the intestinal villi, the endocrine glands, and other tissues and organs where rapid transfer of fluids occurs. In addition to containing the pinocytotic vesicular caveolae, the endothelial cells that form these capillaries have cytoplasmic zones, frequently adjacent to the nuclei of the cells, that characteristically are exceedingly narrow. At these sites the endothelial cells are so thin that a series of fenestrations or pores about  $1,000\text{ }\text{\AA}$  in diameter perforates the cells. The perforations are actually covered by a fine diaphragm, which is thinner than the cell membrane and effectively allows water and solutions to pass readily through the cell.

## VEINS

The veins return blood to the heart from tissues and organs throughout the body. Their walls are thinner but their lumina are larger than those of their accompanying arteries, and although the structure of veins varies, usually they have the same three layers as do arteries: **tunica intima**, **tunica media**, and **tunica adventitia**. Venous blood is under less pressure than arterial blood and it flows more slowly; therefore, at various sites veins contain thin membranous **valves** to prevent the blood from flowing backward toward the capillary bed and away from the heart. Like arteries, veins are supplied with nutrient vessels, the **vasa vasorum**. They also are innervated, but they receive fewer nerve fibers than arteries. Generally, veins are distinguished by size as either small-caliber venules, medium-sized veins, or large venous trunks.

**Fig. 9-47.** Electron micrograph of an arteriole from the human pyloric antrum. The lumen of the arteriole (Alu) is lined by two endothelial cells interconnected at junctions (j). A smooth muscle cell is shown outside the basal lamina (Bl) of the endothelium. Surrounding this are the basal lamina and collagenous connective tissue layer (Cf). N, nucleus; v, vesicles; Cp, cytoplasmic processes; c, centrioles; m, mitochondria; Fc, fibrocyte; Gl, glycogen; Mm, smooth muscle of stomach wall; R, red blood cell. (From Ebe, T. and Kobayashi, S., *Fine Structure of Human Cells and Tissue*, John Wiley and Sons, New York, 1972.)

**FIG. 9-48.** Cross section of a capillary in the lamina propria of the gastric mucosa. The capillary is formed by an endothelial cell surrounded by a basement membrane (Bm). Note the numerous pinocytotic vesicles (Pi) along the membrane of the endothelial cell and the fenestrations (Fe), each of which is bridged by a thin diaphragm. Nu, nucleus; Go, Golgi complex; Mi, mitochondria; Er, erythrocyte; Th, thrombocyte. 30,000  $\times$ . (From Rhodin, J. A. G., *An Atlas of Ultrastructure*, W. B. Saunders Co., Philadelphia, 1963.)

**FIG. 9-49.** Electron micrograph of a portion of endothelial membrane in a capillary, showing surface pinocytotic vesicles ( $V_1$ ,  $V_2$ ) bridged by diaphragms consisting of a single layer ( $d_1$ ) or probably more than one layer ( $d_2$ ). A closed vesicle within the endothelial cytoplasm is shown as  $V_3$ . (From Bruns and Palade, *J. Cell Biol.*, 37: 244-276, 1968.)

**FIG. 9-50.** Intercellular junctions between pairs of endothelial cells, showing regions of constriction (X), the basement membrane (BM), the external (EL) and internal (IL) leaflets of the unit membrane. The lumen of the capillary is indicated by L. 160,000 X. (From Luft, J. H., *Capillary Permeability in The Inflammatory Process*, 2nd ed., Zweifach, B. W., Grant, L., and McCluskey, R. T. (eds.), Vol. 2, Academic Press, New York, 1973.)

### Venules

The venules are the smallest veins, and they are formed by the union of several capillaries. They are larger than capillaries, measuring as much as 20 or 25  $\mu\text{m}$ , and they are importantly involved in the transfer of substances between the body fluids and the vascular system. Although their walls resemble those of capillaries, there is a thin layer of collagenous fibrils and fibroblasts oriented longitudinally outside the endothelium. It is difficult, however, to distinguish the three separate layers in the walls of the smallest venules. In the walls of slightly larger venules (i.e., those with diameters of 50 to 60  $\mu\text{m}$ ) are found a few smooth muscle cells interposed between the endothelial cells and the connective tissue strands that form the tunica adventitia. In many of these larger venules the smooth muscle cells do not form a complete layer around the endothelium. In veins that measure 200 to 400  $\mu\text{m}$  in diameter, the three coats become recognizable and even thin elastic fibers are seen interwoven with the collagenous fibers of the tunica adventitia.

### Veins of Medium Size

The walls of medium-sized veins may vary somewhat in their structure, but usually the three coats can be identified (Figs. 9-42; 9-51). The endothelial cells of the **tunica intima** in these veins contain nuclei that are more oval and less flattened than those in arteries. These cells are supported by delicate connective tissue, external to which is a network of elastic fibers that takes the place of the fenestrated membrane of the arteries. The **tunica media** is usually thinner than that of accompanying arteries, and it is composed of circularly arranged smooth muscle cells, intermingled with collagenous and elastic fibers (Fig. 9-45). At times there is a blending of the connective tissue elements of the innermost and middle coats, and a true definition of the border between them is not readily seen. The **tunica adventitia** consists of loose connective tissue with longitudinal elastic fibers, and it is usually the thickest coat (Figs. 9-42; 9-45).

### Large Veins

In large veins the **tunica adventitia** may be several times thicker than the tunica media and it constitutes a major part of the vessel

wall. The tunica adventitia consists of loose connective tissue that contains elastic fibers and longitudinally oriented collagenous fibers. Within the adventitia are also found layers of longitudinally coursing smooth muscle fibers. These are most distinct in the inferior vena cava (especially at its termination in the heart), in the trunks of hepatic veins, in all the large trunks of the portal vein, and in the external iliac, renal, and azygos veins. In the inferior vena cava, renal, and portal veins, the muscle fibers extend through the whole thickness of the outer coat, but in the other veins mentioned, a layer of connective and elastic tissue is found external to the muscular fibers. The large veins that open into the heart are covered for a short distance by a layer of cardiac muscle from the heart. *Muscular tissue is lacking in the following:* (a) veins of the maternal part of the placenta, (b) venous sinuses of the dura mater and veins of the pia mater of the brain and spinal cord, (c) veins of the retina, (d) veins of the cancellous tissue of bones, and (e) venous spaces of the corpora cavernosa. Veins at these sites consist of an internal endothelial lining supported on one or more layers of loose connective tissue.

**VALVES OF THE VEINS.** Many veins are provided with valves to prevent the reflux of blood (Fig. 9-52). Each valve is formed by a reduplication of the tunica intima which is strengthened by connective tissue and elastic fibers. The valve is covered on both surfaces with endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next to the wall of the vein, the endothelial cells are arranged transversely, while on the other surface, over which the current of blood flows, the cells are arranged longitudinally in the direction of the current. Most commonly two such valves are found placed opposite each other. This is especially so in the smaller veins or in the larger trunks at the points where they are joined by smaller tributaries; occasionally there are three valves and sometimes only one. The valves are semilunar, and are attached by their convex edges to the wall of the vein. The concave margins are free, directed in the course of the venous current, and lie in close apposition with the wall of the vein so long as the current of blood flows in its natural course toward the heart. If, however, any regurgitation occurs, the valves become distended, their opposed

**FIG. 9-51.** Electron micrograph of a posterior abdominal vein in a seven-month-old fetus. This vein shows quite clearly the three layers forming the wall of the vessel. The endothelial cells (E) of the tunica intima rest upon a basal lamina (Bl). Surrounding these is a single layer of smooth muscle cells (Sm) that forms the tunica media. The tunica adventitia is a thicker layer of collagenous connective tissue fibers (Cf), among which are fibrocytes (Fc). Vlu, lumen; Vv, vas vasorum; j, junction between endothelial cells. 15,000  $\times$ . (From Ebe, Y. and Kobayashi, S., *Fine Structure of Human Cells and Tissues*, John Wiley and Sons, Inc., New York, 1972.)

**FIG. 9-52.** The proximal portions of the femoral and great saphenous veins laid open to show the valves. About two-thirds natural size.

edges are brought into contact, and the backward flow is interrupted. The wall of the vein on the cardiac side of the point of attachment of each valve is expanded into a pouch or sinus that gives the vessel a knotted appearance when injected or distended with blood. Valves are numerous in the veins of the limbs, especially the lower limbs, because these vessels must conduct blood against the force of gravity. They are absent in the very small veins and also in the venae cavae, hepatic, renal, uterine, and ovarian veins. A few valves are found in the testicular veins, and one also at their points of junction with the renal vein or inferior vena cava. The cerebral and spinal veins, the veins of cancellous bone, the pulmonary veins, and the umbilical vein and its branches are also destitute of valves. A few valves are occasionally found in the azygos and intercostal veins. Rudimentary valves are found in the tributaries of the portal venous system.

## The Lymphatic System

The **lymphatic system** is a vascular network of thin-walled capillaries and larger lymphatic vessels that drains lymph from the tissue spaces of most organs and returns it to the venous system for recirculation. Peripherally, the lymphatic vessels do not communicate with the blood vessels, but the lymph eventually empties into the bloodstream at the junction of the jugular and subclavian veins at both sides of the neck. The endothelium of the veins at these points of junction is continuous with that of the lymphatic vessels.

Lymphatic fluid is an ultrafiltrate of blood that contains plasma proteins, and during its course it circulates through lymphatic tissue and lymph nodes that are lined with phagocytes capable of removing foreign matter. Additionally, many lymphocytes enter the lymphatic fluid at these nodes, as do the immunoglobulins or antibodies that are so important for immunologic protection. Lymph draining from different organs can vary significantly in its constituents. From the intestines it may have a white milky ap-

pearance and contain a high level of digested fatty substances, whereas from the liver it may be rich in proteins.

The pervasive nature of the lymphatic capillary system, so vital for the system to perform its beneficial functions, may also prove to be dangerous because its channels serve as a means by which bacteria are able to spread quickly throughout the body, with the result of generalized infection. Likewise, the lymphatic system furnishes pathways for the spread of malignant diseases, allowing routes for the establishment of metastatic tumors in other tissues and organs from a primary cancer site. The enormous clinical importance of the lymphatic system is widely recognized today, and yet the study of the system in the dissecting room is unsatisfactory because the thinness of its vascular walls and the small size of its channels make them indistinguishable from the surrounding connective tissues. Thus, most of the information concerning the anatomy of the system has been obtained by laborious special investigations using the injection of colored substances into the minute vessels. Injection into the larger vessels is ineffective because of the presence of numerous valves.

The lymphatic system consists of: (1) an extensive capillary network that collects lymph peripherally from various organs and tissues; (2) an elaborate system of collecting vessels that carries the lymph from the lymphatic capillaries to the bloodstream through an opening into the great veins at the root of the neck; (3) a number of firm, rounded bodies called lymph nodes, placed like filters in the paths of the collecting vessels; (4) certain lymphatic organs that resemble the lymph nodes, such as the tonsils and the aggregated lymphatic tissue found in the walls of the alimentary tract; (5) the spleen; and (6) the thymus. Another element that might be added is the lymphoid tissue, recognizable only with the aid of a microscope and consisting of reticular or areolar connective tissue that contains an accumulation of lymphocytes but lacks the organization of lymphatic nodules.

The spleen serves as an important lymphoid organ, performing phagocytic functions as well as being an organ in which circulating antigens activate appropriate lymphocytes to become functioning immunologic cells. The thymus, important early in life as a

lymphoid organ, produces the so-called T lymphocytes, which participate in cell-mediated immunologic responses. Providing for the proper development of a competent immunologic system, the organ is of greater significance for the maturing child than for the adult.

The lymphatic capillaries and collecting vessels are lined throughout by a continuous layer of endothelial cells, thus forming a closed system. The lymphatic vessels of the small intestine receive the special designation of **lacteals** because they transport the milk-white fluid called **chyle**, but they do not differ morphologically from other lymphatic vessels.

Lymphatic vessels are not found in avascular structures such as the nails, hair, cornea, or epidermis, nor are they found in the central nervous system, meninges, eyeball, internal ear, or spleen.

## Development of Lymphatic System

The precise manner by which the development of the lymphatic system commences is still incompletely understood; however, two views have been forwarded. According to one view, the earliest lymphatic vessels arise from the endothelium of veins as sprouts that coalesce to form **primitive lymph sacs**. Proponents of this view feel that these initial lymphatic plexuses, derived from the veins, then spread to surrounding tissues and organs to form a lymphatic network (Sabin, 1902, 1904, 1912, 1916; Yoffey and Courtice, 1970). Another view maintains that the initial lymphatic sacs arise in mesenchyme independent of the veins, and only secondarily establish venous connections (Huntington and McClure, 1910; Huntington, 1908). Regardless of the specific manner by which the earliest lymphatic sacs are formed, the two **jugular lymph sacs**, one on each side, form during the sixth week near the junction of the subclavian and anterior cardinal veins (Fig. 10-1). From these sacs lymphatic capillary plexuses spread to the neck, head, arms, and thorax. The more direct channels of the plexuses enlarge and form the lymphatic vessels. The larger vessels acquire smooth muscular coats with nerve connections and exhibit contractility. Each jugular sac establishes at least one con-

**Fig. 10-1.** Schema showing relative positions of primary lymph sacs based on the description given by Sabin (1916).

nection with its jugular vein, and from the left sac the upper part of the thoracic duct develops.

At a slightly later stage (eighth week), another lymphatic sac, the retroperitoneal lymph sac, forms near the primitive inferior vena cava and mesonephric veins. From it lymphatics spread to the abdominal viscera and diaphragm, and the sac establishes connections with the cisterna chyli by the end of the ninth week. Also during the eighth week, another unpaired lymphatic sac, the **cisterna chyli**, forms near the Wolffian bodies. Giving rise to the adult cisterna chyli and the lower part of the thoracic duct, it joins that part of the duct that develops from the left jugular sac (Fig. 10-2).

By the end of the eighth week, the paired **posterior lymph sacs** appear near the junctions of the primitive iliac veins and the posterior cardinal veins. From these sacs, lymphatics spread to the abdominal wall, pelvic region, and legs. The posterior lymphatic sacs join each other by the end of the ninth week and also link superiorly with the cisterna chyli (Fig. 10-2). The adult main lymphatic duct forms by means of a diagonal junction of the inferior part of the right lymphatic trunk (connected caudally with the dilated cisterna chyli) and the upper part of the left lymphatic trunk (continuous superiorly with the left jugular sac).

**Fig. 10-2.** Development of the primary lymphatic vessels in man. A, Profile reconstruction of the lymphatic system in a nine-week-old human embryo (Sabin, 1916). B, Diagram of the definitive thoracic duct emerging from a lymphatic plexus. (From Arey, L. B., *Developmental Anatomy*, 7th ed., W. B. Saunders Co., Philadelphia, 1965.)

**DEVELOPMENT OF LYMPH NODES.** The primary lymph nodes begin to develop during the third month in capillary lymphatic plexuses that are formed from the large lymph sacs. Secondary lymph nodes develop later, and even after birth, in peripherally located capillary lymphatic plexuses. Lymphocytes are already present in the bloodstream and tissues long before lymph nodes begin to appear. The earliest stages of lymph node development are obscure, but it seems probable that lymphocytes lodge in special regions of the capillary plexuses and multiply to form larger and larger masses that become the cortical lymphoid nodules and medullary cords. Parallel with this multiplication of lymphocytes, the surrounding mesenchyme forms a connective tissue capsule from which trabeculae carrying blood vessels grow into the lymphoid tissue. Collagenous fibers form in the larger trabeculae, and these continue as reticular fibrils into the smaller trabeculae. The mesenchymal cells

of the larger trabeculae become fibroblasts, and those accompanying the reticular fibrils are known as reticular cells. Just what happens to the lymphatic endothelium of the capillary plexus within the developing node is obscure. Some authors believe that it forms the cortical and medullary sinuses. Others believe that the endothelial lining becomes incomplete and that the reticular cells are washed by the lymph. With this idea goes the theory that some of the reticular cells become spherical to form the first lymphocytes of the developing node and that they retain this potency throughout life.

## Distribution of Lymphatic Vessels

The vessels that form the lymphatic system consist of extensive **capillary plexuses** that drain into an intricate system of **collect-**

ing lymphatic vessels. These, in turn, flow into larger lymphatic trunks that end in the cisterna chyli, the thoracic duct, or the right lymphatic duct (Fig. 10-3).

**LYMPHATIC CAPILLARY PLEXUSES.** The capillary plexuses that collect lymph from the intercellular fluid constitute the beginning of the lymphatic system, because it is from these plexuses that the lymphatic collecting vessels arise. These collecting vessels conduct the lymph centrally through one or more lymph nodes to the lymphatic trunks, cisterna chyli, thoracic duct, or right lymphatic duct. The number, size, and richness of the capillary plexuses differ in different regions and organs. Where abundant, they usually are arranged in two or more anastomosing layers. Most lymphatic capillaries do not contain valves.

Lymphatic capillaries are especially abundant in the **dermis of the skin**. They form a continuous network beneath the epidermis throughout the entire body, with the exception of the cornea. The dermis has a superficial plexus, without valves, that is connected by many anastomoses to a somewhat wider, coarser deep plexus with a few valves. The superficial plexus sends blind ends into the dermal papillae. The plexuses are especially rich over the palmar surface of the hands

and fingers, the plantar surface of the feet and toes, the conjunctiva, the scrotum, the vulva, and around orifices where the skin becomes continuous with mucous membranes (Fig. 10-4).

Lymphatic capillary plexuses are abundant in the **mucous membranes of the respiratory and digestive systems**. They form a continuous network from the nares and lips to the anus. In most places there is a subepithelial plexus in the mucosa that anastomoses freely with a coarser plexus in the submucosa. Blind ends extend between the tubular glands of the stomach and into the villi of the intestine. The latter are the **lacteals**. They have a smooth muscle coat and are contractile. Those portions of the alimentary canal that are covered by peritoneum have a subserous capillary plexus beneath the mesothelium that anastomoses with the submucosal set.

The **lungs** have a rich subserous plexus that connects with the deep plexuses within the lungs. The latter accompany the bronchi and bronchioles but their capillaries do not extend to the alveoli.

The **salivary glands, pancreas, and liver** possess deep lymphatic plexuses. They are perilobular and do not extend between the epithelial cells. The **gallbladder**, and the **cys-**

**FIG. 10-3.** Schema of the larger lymphatic channels in the body. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 10th ed., Urban and Schwarzenberg, 1975.)

**FIG. 10-4.** Lymphatic capillaries of the dermis from the medial border of the sole of the human foot. Note the finer capillaries of the superficial plexus (a) and the larger vessels in the deeper plexus (b). 30  $\times$ . (From Teichmann.)

tic, hepatic, and common bile ducts have rich plexuses in the mucosa. The deep lymphatics of the liver deliver a copious supply of lymph. The liver and gallbladder have rich subserous plexuses.

The **kidney** has a rich network in the capsule and a deep plexus between the tubules of the parenchyma. The renal pelvis and the ureters have rich networks in the mucosa and muscular layer that are continuous with similar plexuses of the **urinary bladder**. The male **urethra** has a dense plexus in the mucosa. The lymphatic capillaries are especially abundant around the navicular fossa.

The **testis**, **epididymis**, **ductus deferens**, **seminal vesicles**, and **prostate** have superficial capillary plexuses. Both the testis and prostate have deep interstitial plexuses.

The **ovary** has a rich capillary plexus in the parenchyma. Capillaries are absent in the tunica albuginea. The **uterine tubes** and **uterus** have mucous and muscular plexuses, as well as serous and subserous ones. The **vagina** has a rich fine-meshed plexus in the mucosa and a coarser one in the muscular layer.

Lymphatic capillary plexuses are abundant beneath the **mesothelial lining** of the pleural, peritoneal, and pericardial cavities and the joint capsules. The dense connective tissues of **tendons**, **ligaments**, and **periosteum** are richly supplied with plexuses. Very fine capillary plexuses around the fibers of

**skeletal muscle** have been described. Their occurrence in **bone** and **bone marrow** is not settled.

The **heart** has a rich subepicardial plexus as well as a subendocardial plexus. The myocardium has a uniform capillary plexus that anastomoses with both the subendocardial and subepicardial ones. There are no collecting trunks in the myocardium.

**COLLECTING LYMPHATIC VESSELS AND LYMPHATIC TRUNKS.** Lymph drains from the lymphatic capillary plexuses into collecting lymphatic channels that resemble venules and enter lymph nodes as afferent vessels. From these initial nodes, several collecting lymphatic vessels join to form slightly larger collecting channels, which then accompany larger blood vessels and enter a series of lymph nodes in succession and anastomose frequently. These larger collecting lymphatic vessels often extend over long distances without a change of caliber. They are exceedingly delicate, and their coats are so transparent that lymph can readily be seen through them. The walls of collecting vessels are interrupted at intervals by constrictions, which correspond to the location of valves on their interior, and give the vessels a knotted or beaded appearance.

At certain sites in the body, groups of collecting vessels course in a parallel manner to form **lymphatic trunks**. These are especially seen along routes leading to the cisterna

chyli and toward the termination of the right lymphatic and thoracic ducts. Leading into the cisterna chyli are the **intestinal trunk** and the **right and left lumbar trunks**, while the right lymphatic duct and the thoracic duct both receive the **bronchomediastinal, jugular, and subclavian trunks** on their respective sides, near the junctions of the two ducts with the venous system.

Lymphatic vessels are arranged in **superficial and deep sets**. The **superficial lymphatic vessels** are placed immediately beneath the integument, accompanying the superficial veins. They join the deep lymphatic vessels at certain sites by perforating the deep fascia. The **deep lymphatic vessels**, fewer in number but larger than the superficial, accompany the deep blood vessels.

In the interior of the body, lymphatic vessels lie in the submucous areolar tissue throughout the whole length of the digestive, respiratory, and genitourinary tracts, and in the subserous tissue of the thoracic and abdominal walls. Plexiform networks of minute lymphatic vessels are found interspersed among the parenchymal elements and blood vessels of the several tissues. The lymphatic vessels that compose the network, as well as the meshes between them, are much larger than those of the capillary plexus. From these networks small vessels emerge and pass either to a neighboring node or join some larger lymphatic trunk.

The lymphatic vessels in any region of the body or in any organ exceed the veins in number, but they are much smaller in diameter. Their anastomoses, especially those of the large trunks, are also more frequent. These anastomoses are effected by vessels equal in diameter to those that they connect, and the continuing trunks retain the same diameter.

## Microscopic Structure of Lymphatic Vessels and Lymph Nodes

The lymphatic vessels are channels through which lymphatic fluid from tissue spaces passes in a one-way direction into the venous system. Along the course of the lymphatic vessels are located encapsulated accumulations of lymphatic tissue, the lymph nodes, within which the lymphocytes are formed.

## STRUCTURE OF LYMPHATIC VESSELS

**LYMPHATIC CAPILLARIES.** Lymphatic capillaries are thin, endothelial-lined channels whose walls are even more delicate than those of capillaries of the blood vascular system (Fig. 10-5). Frequently the contiguous edges of adjacent endothelial cells overlap, and fine *anchoring filaments* of collagen appear to attach the outer surface of the endothelium to the surrounding tissue. Lymphatic capillaries do not possess a well-developed basal lamina, and not only do they allow the passage of extracellular fluids through their walls, but they also absorb back into the circulation considerable amounts of proteins that have escaped into the interstitial spaces.

**LARGER LYMPHATIC VESSELS.** Lymphatic vessels whose diameters measure 1 to 2 mm are considered to be collecting vessels, and their walls are somewhat thicker and better defined than those of lymphatic capillaries. Nonetheless, they are readily distinguishable from blood vessels because their walls are considerably thinner than those of arteries and veins of comparable diameter. The walls of lymphatic vessels that measure more than 2 mm in diameter are composed of three layers, similar to those of blood vessels, but the boundaries of these tunics are not easily distinguishable.

The *internal coat* is thin, transparent, and slightly elastic, consisting of a layer of elongated endothelial cells with wavy margins by which the contiguous cells are dovetailed. The endothelial cells are supported on an elastic membrane. The *middle coat* is composed of smooth muscle cells that are disposed in a circular or oblique manner, and fine elastic fibers that are oriented in a transverse direction. The *external coat* is fairly well developed and consists of connective tissue intermixed with smooth muscle fibers that course longitudinally or obliquely. This adventitia forms a protective covering over the other coats, and connects the vessel with the neighboring structures.

The **thoracic duct** is the largest of the lymphatic vessels, measuring about 0.5 cm in diameter. Its wall is somewhat more complex than that of other lymphatic vessels, having a *tunica intima* that consists of endothelial cells, deep to which are collagenous and elastic fibers. The subendothelial elastic fibers form an *internal elastic membrane*

**FIG. 10-5.** An electron micrograph of a lymphatic capillary in cross-section. Note the close association of the surrounding connective tissue (CT) with the capillary wall which is maintained by anchoring filaments (af). The extreme narrowing (arrows) achieved by the endothelium is illustrated at several regions of the capillary wall. Observe that the nucleus (n) protrudes into the capillary lumen. nu: nucleolus; i: several intercellular junctions; m: mitochondria. 11,000  $\times$ . (From Leak, 1970).

similar to that found in the arteries. In the *tunica media* there is, in addition to muscular and elastic fibers, a layer of connective tissue with longitudinally arranged fibers. The *tunica adventitia* consists of both connective tissue and bundles of smooth muscle fibers, and it tends to blend with surrounding connective tissue.

The larger lymphatic vessels are supplied by **nutrient vessels**, which are distributed to their outer and middle coats, as well as by unmyelinated nerve fibers, which form fine plexuses in their wall.

The **valves** of lymphatic vessels are formed by thin layers of fibrous connective tissue, covered on both surfaces by endothelium, and having the same arrangement as the valves in veins. The valves consist of semilunar cusps that are attached by their convex edges to the wall of the vessel, the concave edges being free and directed along the course of the contained current. Usually two such cusps of equal size are found opposite each other, but occasionally exceptions occur, especially at or near the anastomoses of lymphatic vessels. In such cases one cusp may be small and the other proportionately larger. At times, a valve may consist of three cusps. Valves are placed at much shorter intervals in lymphatic vessels than in the veins. They are most numerous near lymph nodes, and are found more frequently in lymphatic vessels of the neck and upper extremity than in those of the lower extremity. The wall of the lymphatic vessel immediately above the point of attachment of each cusp of a valve is expanded into a pouch or sinus that gives to these vessels, when distended, a characteristic knotted or beaded appearance. Valves are wanting in the capillaries that compose the plexiform network, from which the larger lymphatic vessels originate. **Lymph** is propelled by contractions of the walls in the larger lymphatic vessels, or by the motion of surrounding structures in smaller vessels. The valves prevent the backward flow of lymph.

### STRUCTURE OF LYMPH NODES

**Lymph nodes** are small oval or bean-shaped bodies that are situated along the course of lymphatic vessels so that lymph will filter through them on its way to the blood. Each node generally has a slight de-

pression on one side, the **hilus**, through which the blood vessels enter and leave (Figs. 10-6; 10-7). The **efferent lymphatic vessels** also emerge from the hilus, while the **afferent lymphatic vessels** enter lymph nodes at various places on the periphery. When a fresh lymph node is transected, it displays a lighter, outer **cortex**, surrounding an inner, darker **medulla**. The boundary between these is indefinite, but at the hilus the cortex is deficient and the medulla extends to the nodal surface (Fig. 10-6). The afferent lymph vessels carry fluid to the nodal periphery, where it achieves the cortex, and after traversing the node, lymph leaves the medulla by way of the efferent lymphatic vessels at the hilus (Fig. 10-7).

Lymph nodes measure 1 to about 30 mm in diameter, and each consists of enormous numbers of **lymphocytes**, **plasma cells**, and **macrophages**, densely packed into masses that are partially subdivided into a series of cortical nodules and medullary cords by anastomosing connective tissue trabeculae, bordered by lymph sinuses. The **trabeculae** extend into the node from the collagenous connective tissue **capsule** and the hilus. An intricate network of **reticular fibers** extends from the trabeculae to form a supporting meshwork for the lymphoid elements (Fig. 10-8). A continuous narrow channel, probably lined by endothelial cells and macrophages, is found just beneath the capsule. From this **subcapsular** or **marginal sinus** arise other radially-oriented sinuses that border the trabeculae; these course through the cortex and medulla and are appropriately called **cortical sinuses** and **medullary sinuses** (Figs. 10-6 to 10-8). The afferent lymphatic vessels open into the subcapsular sinus, and the efferent vessels arise from the medullary sinuses. As lymph slowly passes through this system of channels from afferent to efferent vessels, its flow is retarded by the large numbers of reticular fibers that project across the sinuses in all directions. The elegantly intricate architecture of the lymph node allows the lymphatic fluid an abundant exposure to the lymphoid elements that surround the sinuses, thereby creating an effective means by which foreign elements in the tissue fluids may be detected, attacked, and phagocytosed. Numerous flattened stellate endothelial cells and macrophages cling to the reticular fibers.

The supporting stromal structures of a

**FIG. 10-6.** A cross-section view through a lymph node. Stained with hematoxylin and eosin.  $32\times$ . (From di Fiore, M., *Atlas of Human Histology*, 5th ed., Lea & Febiger, Philadelphia, 1981.)

**Fig. 10-7.** Diagram of a lymph node indicating how the afferent lymphatic vessels open into the subcapsular sinus. Lymph then flows through the cortical sinuses and the medullary sinuses before leaving by way of the efferent lymphatic vessels. (After Bloom and Fawcett, *A Textbook of Histology*, 9th ed., 1968.)

lymph node include the collagenous connective tissue capsule, which also contains networks of elastic fibers and a few smooth muscle cells, its trabecular extensions, and the finer reticular fibers (Figs. 10-8; 10-9). The capsule is thicker at the hilum, where blood vessels enter and leave the node along with their accompanying vasomotor nerve fibers.

The parenchymal tissue of a lymph node is organized within the cortex into dense spherical masses of lymphoid cells, called **primary lymphoid follicles** or **primary nodules** (Figs. 10-6 to 10-8). Within these follicles are frequently found central areas where mitotic nuclei indicate multiplication of the lymphocytes. These areas are termed **germinal centers** or **secondary nodules**. The cells that compose them have more abundant protoplasm than the peripheral cells, and consist of large and medium-sized lymphocytes. Other, more diffusely disseminated lymphoid tissue is found between the primary follicles in the cortex of the node (Figs. 10-8; 10-9). Within the medulla, the lymph-

oid tissue is even more diffuse and helps to form the **medullary cords** that are oriented toward the hilus. These cords are aggregations of lymphocytes, plasma cells, and macrophages that usually surround blood vessels and reticular fibers.

**HEMAL NODES.** Although a few red blood cells are normally found in lymph nodes, hemal nodes contain exceptionally large numbers of erythrocytes. They are found in certain animals, notably ruminants, but probably only occur as pathologic structures in man. Hemal nodes are quite small and resemble lymph nodes in structure, but are likely to be without afferent and efferent lymphatic vessels and are engorged with blood.

**LYMPH.** Although lymph should be defined as the fluid within the walls of a closed system consisting of the lymphatic vessels, it should be understood that the composition of the lymph found in a regional set of lymphatics is nearly identical with that of the interstitial or tissue fluid of the region being

**Fig. 10-8.** This is a photomicrograph of a human lymph node showing the capsule, the subcapsular sinus and portions of two primary lymphoid follicles which are separated by a darkly impregnated connective tissue trabecula. 360  $\times$ . (Counterstained silver preparation.)

drained. Thus, lymphatic fluids derived from different parts of the body have different chemical compositions. Interstitial fluid has an average protein concentration of 2 gm/100 ml, as does lymph; however, lymph drained from the liver and intestines may have protein levels two to three times higher, and after a fatty meal, lymph from the intestinal lacteals may have a fat concentration high enough to make the fluid milky white.

Frequently, lymph has been called an ultrafiltrate of blood plasma, but the important issue is that lymphatic capillaries are capable of reabsorbing proteins, a process that does not occur to any appreciable degree at the venule end of the blood capillary system. Although venules reabsorb water, the proteins that leak into the interstitial spaces remain behind in the tissues. Unless reabsorption of proteins by the lymphatic capil-

laries occurs, death can follow in one or two days.

Lymph that drains from the limbs is generally a colorless or slightly yellow watery fluid with a specific gravity slightly over 1. When examined under the microscope, leukocytes of the lymphocyte class are found floating in the transparent fluid. They always increase in number after the passage of the lymph through lymphoid tissue, as in lymph nodes.

## Large Lymphatic Vessels

### THORACIC DUCT

The **thoracic duct** conveys a greater part of the lymph in the body back into the blood vascular system (Figs. 10-10; 10-22). It is the

**FIG. 10-9.** High magnification of a portion of the subcapsular sinus and primary lymphoid follicle in the lymph node shown in Figure 10-8. Note the meshwork of reticular fibers and dense masses of lymphoid tissue which characterize the follicle and the looser lymphoid elements in the subcapsular sinus. 900  $\times$ . (Counterstained silver preparation.)

common trunk of all the lymphatic vessels except those on the right side of the head, neck, and thorax, the right upper limb, the right lung, right side of the heart, and the diaphragmatic surface of the liver. In the adult, the thoracic duct varies in length from 38 to 45 cm and extends from the second lumbar vertebra to the root of the neck. It begins in the abdomen by a dilatation, the **cisterna chyli**, which is situated on the anterior surface of the body of the first and second lumbar vertebrae, to the right side of and behind the aorta, and adjacent to the right crus of the diaphragm. The duct then enters the thorax through the aortic hiatus of the diaphragm, and ascends through the posterior mediastinum between the aorta and azygos vein. *Dorsal* to it in this region are the vertebral column, the right intercostal arteries, and the hemiazygos veins, which cross the midline to open into the azygos

vein. *Ventral* to it are the diaphragm, the esophagus, and the pericardium, the latter being separated from the duct by a recess in the right pleural cavity.

Opposite the fifth thoracic vertebra, the thoracic duct inclines toward the left side and enters the superior mediastinum. Its ascent in the thorax continues to the thoracic inlet, dorsal to the aortic arch and the thoracic part of the left subclavian artery, and between the left side of the esophagus and the left pleura.

Passing into the root of the neck on the left side, the thoracic duct forms an arch that rises about 3 or 4 cm above the clavicle, crossing anterior to the subclavian artery, the vertebral artery and vein, and the thyrocervical trunk or its branches. It also passes ventral to the phrenic nerve and the medial border of the scalenus anterior muscle, and dorsal to the left common carotid artery,

Fig. 10-10. The thoracic and right lymphatic ducts.

vagus nerve, and internal jugular vein. It terminates by opening into the angle of junction of the left subclavian vein and the left internal jugular vein.

The thoracic duct is about 3 to 5 mm in diameter at its commencement, but its caliber diminishes considerably in the middle of the thorax, and again dilates just before its

termination. It is generally flexuous and constricted at intervals and presents a varicose appearance. Not infrequently, it divides in the middle of its course into two vessels of unequal size that soon reunite, or into several branches that form a plexiform interlacement. It occasionally divides in the upper part of its course into two branches, right and left, the left ending in the usual manner, while the right opens into the right subclavian vein with the right lymphatic duct.

The thoracic duct has several valves. At its junction with the venous system, it has a bicuspid valve, and the free borders of the cusps of this valve are directed toward the vein to prevent the reflux of venous blood into the duct.

**CISTERNA CHYLI.** The cisterna chyli is a dilated sac anterior to the bodies of the two uppermost lumbar vertebrae; it forms the origin of the thoracic duct (Figs. 10-10; 10-11). It lies lateral to the right crus of the diaphragm, and it receives the right and left lumbar lymphatic trunks, along with the intestinal lymphatic trunks. The **lumbar trunks** are formed by the union of the efferent vessels from the lateral aortic lumbar lymph nodes. They receive lymph from the lower limbs, the walls and viscera of the pelvis, the kidneys, suprarenal glands, ovaries or testes, and the deep lymphatics of the greater part of the abdominal wall. The **intestinal trunks** consist of large lymphatic vessels that receive lymph from the stomach and intestine, the pancreas and spleen, and the visceral surface of the liver.

#### *Tributaries of the Thoracic Duct*

Opening into the thoracic duct near the cisterna chyli, on each side, is a descending trunk from the posterior intercostal lymph nodes that drains the lower six or seven intercostal spaces. On each side of the thorax, the duct is joined by a trunk that drains the upper lumbar lymph nodes and pierces the crus of the diaphragm. It also receives efferent vessels from the posterior mediastinal lymph nodes and from the posterior intercostal lymph nodes of the upper six spaces on the left side. In the neck, it is frequently joined by the **left jugular trunk**, which drains the left side of the head and neck, and the **left subclavian trunk** from the left upper extremity. Sometimes it also receives the **left**

**Fig. 10-11.** Modes of origin of thoracic duct. *a*, Thoracic duct. *a'*, Cisterna chyli. *b*, *c*, Efferent trunks from lateral aortic node. *d*, An efferent vessel which pierces the left crus of the diaphragm. *e*, *f*, Lateral aortic nodes. *h*, Retroaortic nodes. *i*, Intestinal trunk. *j*, Descending branch from intercostal lymphatics. (Poirier and Charpy.)

**bronchomediastinal trunk**; however, this vessel usually opens independently into the junction of the left subclavian and internal jugular veins.

#### RIGHT LYMPHATIC DUCT

The right lymphatic duct measures about 1.25 cm in length. It courses along the medial border of the right scalenus anterior muscle at the root of the neck, and ends in the right subclavian vein, at its angle of junction with the right internal jugular vein. Its orifice is guarded by a bicuspid valve, the two semilunar cusps of which prevent the passage of venous blood into the duct.

#### Tributaries of the Right Lymphatic Duct

The right lymphatic duct receives lymph from the right side of the head and neck through the **right jugular trunk**, from the

right upper extremity through the **right subclavian trunk**, and from the right side of the thorax, right lung, right side of the heart, and part of the convex surface of the liver through the **right bronchomediastinal trunk**. Although a single right lymphatic duct, formed by the junction of these three trunks, occurs at times, more frequently these trunks open separately near the angle of junction of the right internal jugular and right subclavian veins (Fig. 10-12).

### Lymphatic Vessels and Nodes of the Head and Neck

For the most part, lymph that drains from the superficial structures in the head initially flows into superficial vessels and nodes in the upper neck (Fig. 10-13). It is then directed into the deep cervical nodes, which also re-

**Fig. 10-12.** Terminal collecting trunks of right side. *a*, Jugular trunk. *b*, Subclavian trunk. *c*, Bronchomediastinal trunk. *d*, Right lymphatic trunk. *e*, Node of internal mammary chain. *f*, Node of deep cervical chain. (Poirier and Charpy.)

**FIG. 10-13.** Superficial lymph nodes and lymphatic vessels of head and neck.

ceive lymphatic channels from deeper structures in the face and head, as well as from the deeper viscera of the neck. In the deep neck the lymphatic vessels join to form the jugular trunk, which on the right side joins the right lymphatic duct or opens directly into the right subclavian vein, and on the left side joins the thoracic duct. The following description will consider first the lymphatic vessels and lymph nodes of the head, and then the lymphatic vessels and nodes of the neck.

#### LYMPHATIC VESSELS OF THE HEAD

The lymphatic vessels of the head include those that drain the scalp, external ear, face, walls of the nasal cavity, and mouth, as well as those of the walls of the oral cavity, palatine tonsils, and tongue.

**LYMPHATIC VESSELS OF THE SCALP.** The lymphatic vessels that drain the scalp include those from the temporoparietal region and those that drain the occipital region (Fig. 10-13). The **temporoparietal vessels** end in superficial parotid and retromandibular nodes, while the **occipital vessels** terminate partly in the occipital nodes and partly in a trunk that runs downward along the posterior border of the sternocleidomastoid muscle and ends in the inferior deep cervical nodes. Lymphatic vessels that drain the frontal region of the scalp above the nose will be considered with the facial channels.

**LYMPHATIC VESSELS OF THE EXTERNAL EAR.** The lymphatic vessels draining the auricula of the external ear and the walls of the external acoustic meatus are also divisible into three groups: anterior, posterior, and inferior. The **anterior auricular vessels** drain the lateral surface of the pinna and the anterior

wall of the meatus and flow to the anterior auricular nodes, situated immediately in front of the tragus. The **posterior auricular vessels** drain the margin of the auricula and the upper part of its cranial surface, and the internal surface and posterior wall of the meatus, and flow to the posterior auricular and superior deep cervical nodes. The **inferior auricular vessels** from the floor of the external acoustic meatus and the lobule of the auricula drain downward into superficial and superior deep cervical nodes.

**LYMPHATIC VESSELS OF THE FACE.** The lymphatic vessels of the face are more numerous than those of the scalp. The **palpebral vessels** from the eyelids and the **conjunctival vessels** drain partly downward to the submandibular nodes, but principally laterally and posteriorly to the parotid nodes (Figs. 10-13; 10-14). Lymphatic vessels from the posterior part of the cheek also pass to the parotid nodes, while those from the anterior portion of the cheek, the side of the nose, the upper lip, and the lateral portions of the lower lip end in the submandibular nodes. The **deep temporal and infratemporal vessels** pass to the deep facial and superior deep cervical nodes. The deeper vessels of the cheek and lips, like the more superficial lymphatics, terminate in the submandibular nodes. Both **superficial and deep labial ves-**

**sels** from the central part of the lower lip course to the submental nodes.

**LYMPHATIC VESSELS OF THE NASAL CAVITY.** From the anterior parts of the walls of the nasal cavity, lymphatic vessels communicate with channels from the integument of the nose, and therefore, end in the submandibular nodes. Lymphatic vessels from the posterior two-thirds of the nasal cavity and the paranasal air sinuses pass partly to the retropharyngeal and partly to the superior deep cervical nodes.

**LYMPHATIC VESSELS OF THE MOUTH.** Lymphatic vessels of the gums pass to the submandibular nodes. Channels that drain the *hard palate* are continuous in front with those of the upper gum, but pass backward to pierce the superior pharyngeal constrictor muscle and end in the superior deep cervical and subparotid nodes. Lymphatic vessels of the *soft palate* pass backward and laterally, and end partly in the retropharyngeal and subparotid nodes, and partly in the superior deep cervical nodes. The vessels of the anterior part of the *floor of the mouth* pass either directly to the inferior nodes of the superior deep cervical group, or indirectly through the submental nodes. Lymphatics from the remainder of the floor of the mouth pass to the submandibular and superior deep cervical nodes.

**FIG. 10-14.** The lymphatics and lymph nodes of the lateral aspect of the face. (After Küttner.)

**Lymphatic Vessels from Palatine Tonsil.**

Usually three to five lymphatic vessels arise from the palatine tonsil. These pierce the buccopharyngeal fascia and the superior pharyngeal constrictor muscle, and pass between the stylohyoid muscle and the internal jugular vein to the most superior deep cervical node (Fig. 10-15). They end in a node, called the **jugulodigastric node**, which lies at the side of the posterior belly of the digastric muscle and adjacent to the internal jugular vein. Occasionally one or two additional vessels course to small nodes on the lateral side of the internal jugular vein, under cover of the sternocleidomastoid muscle.

**Lymphatic Vessels from the Tongue.**

Lymphatic vessels that arise in the tongue drain chiefly into the deep cervical nodes that lie between the posterior belly of the digastric muscle and the superior belly of the omohyoid muscle (Fig. 10-15). One lymph node, situated at the bifurcation of

the common carotid artery and posterior to the internal jugular vein and the omohyoid muscle, is intimately associated with these vessels; it is called the **jugulo-omohyoid node** and has frequently been referred to as the principal node of the tongue. The lymphatic vessels of the tongue can be divided into four groups: **apical** (vessels from the tip of the tongue that course to the suprahyoid nodes and the jugulo-omohyoid node); **lateral** or **marginal** (vessels from the margin of the tongue, some of which pierce the mylohyoid muscle and end in the submandibular nodes, while others pass downward on the hyoglossus muscle to the superior deep cervical nodes) (Fig. 10-16); **basal** (channels from the region of the vallate papillae that travel to the superior deep cervical nodes); and **median** or **central** (a few vessels from the more anterior central region) that perforate the mylohyoid muscle to reach the submental and submandibular nodes, although the majority turn around the posterior bor-

**Fig. 10-15.** The deep cervical lymphatic nodes and vessels of the right upper cervical triangle. The lymphatic drainage of the tongue is shown. (Eycleshymer and Jones.)

der of the muscle and enter both the superior and inferior deep cervical lymph nodes.

It is important to realize that lymphatics from the apical, median, and basal parts of the tongue course to deep cervical nodes on both sides of the neck, whereas lymphatic vessels from the lateral margins of the tongue initially flow to nodes on the same side (Fig. 10-16).

#### LYMPH NODES OF THE HEAD

The lymph nodes of the head are arranged in the following groups:

- Occipital
- Retroauricular
- Superficial parotid
- Deep parotid
- Facial
- Deep facial
- Lingual
- Retropharyngeal

**OCCIPITAL LYMPH NODES.** The occipital lymph nodes, one to three in number, are located on the back of the head, close to the margin of the trapezius muscle, and rest on the insertion of the semispinalis capitis (Figs. 10-13; 10-18). Their afferent vessels drain the occipital region of the scalp, while their efferent vessels pass to the superior deep cervical nodes.

**RETROAURICULAR LYMPH NODES.** The retroauricular lymph nodes, usually two in number, are situated on the mastoid insertion of

the sternocleidomastoid muscle, deep to the posterior auricular muscle (Figs. 10-13; 10-18). Their afferent vessels drain the posterior part of the temporoparietal region, the upper part of the cranial surface of the auricula or pinna, and the posterior part of the external acoustic meatus; efferent vessels pass to the superior deep cervical nodes.

**SUPERFICIAL PAROTID LYMPH NODES.** The superficial parotid or preauricular nodes usually number three or more, and they lie immediately anterior to the tragus of the external ear (Figs. 10-13; 10-14). Their afferent vessels drain the lateral surface of the auricula, external acoustic meatus, root of the nose, eyelids, and frontotemporal region of the scalp, while their efferent vessels pass to the superior deep cervical nodes.

**DEEP PAROTID LYMPH NODES.** The deep parotid lymph nodes are arranged in two groups. One group is embedded in the substance of the parotid gland, and a second group, the subparotid nodes, is located deep to the gland and lies on the lateral wall of the pharynx. These deep parotid nodes receive lymphatic afferents from the parotid gland, the posterior parts of the palate, the floor of the nasal cavity, and the walls of the tympanic cavity of the middle ear; the efferent vessels of these nodes pass to the superior deep cervical nodes. Other afferent vessels to the subparotid nodes drain the nasal part of the pharynx and the posterior parts of the nasal cavities, while the efferent vessels also pass to the superior deep cervical nodes.

**Fig. 10-16.** A diagram to show the course of the marginal and central lymphatic vessels of the tongue to the lymph nodes on both sides of the neck. (Jamieson and Dobson.)

**FACIAL LYMPH NODES.** The facial lymph nodes consist of maxillary, buccal, and mandibular nodes (Fig. 10-13). The **maxillary nodes** are scattered over the infraorbital region, from the groove between the nose and cheek to the zygomatic arch. The **buccal nodes**, one or more, are placed over the buccinator muscle, opposite the angle of the mouth. The **mandibular nodes** lie on the outer surface of the mandible, in front of the masseter muscle and in contact with the facial artery and vein. Their afferent vessels drain the eyelids, the conjunctiva, and the skin and mucous membrane of the nose and cheek, and their efferent vessels pass to the submandibular nodes (Figs. 10-13; 10-14).

**DEEP FACIAL LYMPH NODES.** The deep facial or internal maxillary nodes are placed deep to the ramus of the mandible, on the outer surface of the lateral pterygoid muscle, in relation to the maxillary artery. Their afferent vessels drain the temporal and infratemporal fossae and the nasal part of the pharynx, while their efferents pass to the superior deep cervical nodes.

**LINGUAL LYMPH NODES.** Two or three small lingual nodes are located along the surface of the hyoglossus muscle and under the genioglossus muscle. They serve as substations in the course of the lymphatic vessels of the tongue to the deep cervical nodes.

**RETROPHARYNGEAL LYMPH NODES.** The retropharyngeal lymph nodes, one to three in number, lie in the buccopharyngeal fascia,

behind the upper part of the pharynx and anterior to the arch of the atlas, from which they are separated by the longus capitis muscle (Fig. 10-17). Their afferent vessels drain the nasal cavity, nasal part of the pharynx, and auditory tubes, while their efferent vessels pass to the superior deep cervical nodes.

#### LYMPHATIC VESSELS OF THE NECK

In addition to draining the skin and muscles of the neck, the lymphatic vessels of this region serve the pharynx and upper esophagus, the larynx and upper trachea, and the thyroid gland. Lymphatics from the **skin and strap muscles** of the anterolateral neck drain into the deep cervical nodes.

The lymphatic vessels from the **pharynx** generally drain backward, laterally, and downward, while those from the nasopharynx and pharyngeal tonsil drain to the lateral retropharyngeal nodes (Fig. 10-17). From the oropharynx and palatine tonsil, lymphatics drain to the superior deep cervical chain of nodes, and especially to the jugulodigastric node (Figs. 10-15; 10-18). From the laryngeal pharynx and upper esophagus, lymphatic vessels course in the piriform sinus and paratracheal region to the inferior deep cervical nodes.

Numerous lymphatic vessels drain the **larynx**. They are divided into two sets, a superior and an inferior, by the vocal fold, which

FIG. 10-17. Lymphatics and lymph nodes of the pharynx. (Poirier and Charpy.)

**Fig. 10-18.** The deep lymphatic vessels and nodes on the right side of the head, neck, and axilla.

itself does not contain numerous vessels. The vessels of the superior set pierce the thyrohyoid membrane, course with the superior laryngeal artery, and join the superior deep cervical nodes. The inferior set of la-

ryngeal lymphatic vessels courses along branches of the inferior thyroid artery. Some pierce the conus elasticus and join the pretracheal and prelaryngeal nodes, while others course between the cricoid and first tra-

cheal ring and descend to the inferior deep cervical nodes.

The lymphatic vessels of the **thyroid gland** also consist of superior and inferior sets; these follow the branches of the superior and inferior thyroid artery. The superior set drains the upper margin of the isthmus and the upper parts of the lateral lobes of the gland, and enters the superior deep cervical nodes. The inferior set drains most of the isthmus and the lower parts of the lateral lobes. Both sets descend to the deep inferior cervical nodes by way of both the pretracheal and paratracheal nodes, the latter accompanying the recurrent laryngeal nerves. Lymphatic vessels from the cervical portion of the trachea also drain into these paratracheal nodes. Some lymphatic vessels of the thyroid gland may open directly into the large veins in the root of the neck, or into the thoracic duct.

#### LYMPH NODES OF THE NECK

The lymph nodes of the neck include the following groups:

- Submandibular
- Submental
- Superficial cervical
- Anterior cervical
- Deep cervical

**SUBMANDIBULAR LYMPH NODES.** The submandibular chain of lymph nodes, three to six in number, are located beneath the body of the mandible in the submandibular triangle (Figs. 10-13 to 10-15; 10-18). They usually rest on the superficial surface of the submandibular salivary gland, but may extend as far forward as the border of the anterior belly of the digastric muscle. One node, which lies on the facial artery as it turns over the mandible, is the largest and most constant of the series. Additional small lymph nodes are sometimes found on the deep surface of the submandibular salivary gland. Afferent lymphatic vessels to the submandibular nodes drain the medial palpebral commissure of the eye, the cheek, the side of the nose, the upper lip, the lateral part of the lower lip, the gums and teeth, the anterior part of the margin of the tongue (except the tip), the frontal, maxillary, and ethmoidal sinuses, as well as the efferent vessels from the facial and submental nodes. Thus,

not only superficial integumentary structures, but also mucous membranes, drain into the submandibular nodes, and in turn, their efferent vessels pass to both superficial cervical and superior deep cervical nodes.

**SUBMENTAL LYMPH NODES.** Three or four small submental lymph nodes are found in the submental triangle between the anterior bellies of the digastric muscles (Figs. 10-13; 10-18). Their afferents drain a centrally placed wedge of tissue that includes the incisor region of the lower gum and lips, tip of the tongue, central part of the floor of the mouth, and skin of the chin. Efferent vessels from the submental nodes pass partly to the submandibular nodes, and partly to the deep cervical chain, especially the jugulomohyoid node.

**SUPERFICIAL CERVICAL LYMPH NODES.** The superficial cervical lymph nodes lie in close relationship with the external jugular vein as it emerges from the parotid gland, and therefore are located superficial to the sternocleidomastoid muscle (Figs. 10-13; 10-14). Their afferent vessels drain the lower parts of the external ear and parotid region, while their efferent channels pass around the anterior margin of the sternocleidomastoid muscle to join the superior deep cervical nodes.

**ANTERIOR CERVICAL LYMPH NODES.** The anterior cervical lymph nodes form an irregular and inconstant group located below the hyoid bone and in front of the larynx, trachea, and thyroid gland. They may be divided into a superficial and a deep set. The **superficial set** is placed on the anterior jugular vein and drains the skin of the anterior region of the neck below the hyoid bone. The **deep set** is further subdivided into **prelaryngeal nodes**, which lie on the middle cricothyroid ligament, and **pretracheal nodes**, which are located ventral to the trachea. This deeper set drains the lower part of the larynx, the thyroid gland, and the cervical part of the trachea. Its efferent vessels pass to the most inferior of the superior deep cervical nodes.

**DEEP CERVICAL LYMPH NODES.** The deep cervical lymph nodes are numerous and large, forming a chain of 20 to 30 nodes along the carotid sheath and around the internal jugular vein. Lying by the side of the pharynx, esophagus, and trachea, the deep cervical nodes extend from the base of the skull to the root of the neck. They are usually described in two groups, the superior and inferior deep cervical nodes.

**Superior Deep Cervical Lymph Nodes.** The superior deep cervical nodes are located above the level at which the omohyoid muscle crosses the common carotid artery (Figs. 10-13 to 10-15; 10-17; 10-18). They lie deep to the sternocleidomastoid muscle, in close relationship to the accessory nerve and the internal jugular vein; some of the nodes lie anterior, and others posterior, to the vessel. The superior deep cervical nodes drain the occipital portion of the scalp, the auricula, the back of the neck, a considerable part of the tongue, and the larynx, thyroid gland, trachea, nasal part of the pharynx, nasal cavities, palate, and esophagus. They also receive the efferent vessels from all the other nodes of the head and neck, except the inferior deep cervical nodes. The most superior, and one of the most important of these deep cervical nodes, lies just below the site where the posterior belly of the digastric muscle crosses the internal jugular vein and internal carotid artery. It is called the **jugulodigastric lymph node** and is located in a rather superficial position that allows it to be palpated with ease in the living patient (Fig. 10-18). It is sometimes called the **subdigastric** or **tonsillar node**, and it becomes swollen when the tonsil or pharynx is inflamed, or when there is a cancer on the posterior third of the tongue or the palatine tonsil.

**Inferior Deep Cervical Lymph Nodes.** The inferior deep cervical nodes extend beyond the posterior margin of the sternocleidomastoid muscle and into the supraclavicular triangle, where they are in close relationship to the brachial plexus and subclavian vein (Figs. 10-13; 10-15; 10-18). One large and relatively constant node in this group is the **jugulo-omohyoid lymph node** (Fig. 10-18). It lies on or immediately behind the internal jugular vein, just superior to the tendon of the omohyoid muscle. The inferior deep cervical nodes drain the back of the scalp and neck, the superficial pectoral region, part of the arm, and occasionally part of the superior surface of the liver. In addition, they receive vessels from the tongue and the superior deep cervical nodes. These latter nodes pass partly to the inferior deep cervical nodes, and partly to a trunk that unites with the efferent vessel of the inferior deep cervical nodes to form the **jugular trunk**. On the right side, this trunk ends in the junction of the internal jugular and subclavian veins, while on the left side it joins the thoracic

duct. A few minute **paratracheal nodes** are situated alongside the recurrent laryngeal nerves on the lateral aspects of the trachea and esophagus.

## Lymphatic Vessels and Nodes of the Upper Limb

The lymphatic drainage of the upper limb is directed along the routes of the major blood vascular channels. The superficial lymphatics generally follow the veins, while the deep lymphatics course with the arteries. For the most part, lymph from the upper limb drains to axillary nodes because the arm, forearm, and hand possess very few nodes and those few are exceedingly small.

### LYMPHATIC VESSELS OF THE UPPER LIMB

The lymphatic vessels of the upper limb consist of two sets, superficial and deep.

**SUPERFICIAL LYMPHATIC VESSELS.** The superficial lymphatic vessels of the upper extremity commence in the complex lymphatic plexus that pervades the skin throughout the entire limb. The meshes of the plexus are much denser in the palm of the hand and on the flexor aspect of the digits than elsewhere. The **digital plexuses** are drained by vessels that course along the sides of each finger and incline backward to reach the dorsum of the hand (Fig. 10-19). From the dense **palmar plexus**, vessels pass in different directions, proximally toward the wrist, distally to join the digital vessels, medially to join the vessels on the ulnar border of the hand, and laterally to those on the thumb. Several vessels from the central part of the palmar plexus unite to form a trunk that passes around the metacarpal bone of the index finger to join the vessels on the back of that digit and on the back of the thumb. Continuing proximally from around the wrist, the lymphatic vessels are collected, more or less as parallel channels, into **radial**, **median**, and **ulnar** groups, which accompany, respectively, the cephalic, median, and basilic veins in the forearm (Fig. 10-20). A few of the ulnar lymphatics end in the small **supratrochlear nodes** that are located superficially just above the medial aspect of the cubital fossa, but the majority

**Fig. 10-19.** Lymphatic vessels of the dorsal surface of the hand. (Sappey.)

pass directly to the lateral group of **axillary nodes**. Some of the radial vessels are collected into a trunk that ascends with the cephalic vein to the **deltopectoral nodes** (Figs. 10-20; 10-21). The efferents from this group may penetrate the clavipectoral fascia, with the cephalic vein, to enter the apical group of axillary nodes in the infraclavicular region, or they may ascend as far as the lower deep cervical nodes above the clavicle.

**DEEP LYMPHATIC VESSELS.** The deep lymphatic vessels accompany the deep blood vessels. In the forearm, they consist of four sets, which correspond to the radial, ulnar, anterior, and posterior interosseous arteries. They communicate at intervals with the superficial lymphatics, and some channels end in nodes that are occasionally found with these arteries. Along their ascent proximally in the arm, these deeper lymphatic vessels follow the course of the brachial artery. A few may even terminate in small nodes along these vessels, but most of them pass to the lateral group of axillary nodes.

## LYMPH NODES OF THE UPPER LIMB

For the most part the lymph nodes of the upper limb are grouped in the axilla. However, there exists a set of somewhat isolated, outlying, and more superficial nodes, which are small and receive afferent lymphatic vessels from some of the ascending channels of the forearm and arm. Therefore, the lymph nodes of the upper extremity will be described as consisting of superficial and deep sets.

**SUPERFICIAL LYMPH NODES.** The superficial lymph nodes in the upper extremity are few and small, and they are located either deep to the epidermis or in the underlying superficial fascia, closely associated with large superficial veins. They include both supratrochlear and deltopectoral nodes.

**Supratrochlear Nodes.** One or as many as five small supratrochlear nodes are present in the superficial fascia, above the medial epicondyle of the humerus, medial to the basilic vein (Fig. 10-20). Their afferents drain the middle, ring, and little fingers, the medial portion of the hand, and the superficial area over the ulnar side of the forearm, but these vessels are in free communication with the other lymphatic vessels of the forearm. Their efferent vessels also accompany the basilic vein and some join the deeper vessels.

**Deltopectoral Nodes.** One or two deltopectoral nodes are found beside the cephalic vein and within the deltopectoral triangle, between the pectoralis major and deltoid muscles, immediately below the clavicle.

**DEEP LYMPH NODES.** The deep lymph nodes are chiefly grouped in the axilla, although a few tiny nodes may be found in the forearm, along the course of the radial, ulnar, and interosseous arteries, and in the arm along the medial side of the brachial artery.

**The Axillary Nodes.** The axillary lymph nodes (Fig. 10-21) are large, vary from 20 to 30 in number, and are arranged in the following groups:

- Lateral
- Pectoral (anterior)
- Subscapular (posterior)
- Central
- Apical (subclavicular)

**Lateral Group.** The lateral group consists of four to six axillary nodes that are located

**FIG. 10-20.** The superficial lymph nodes and lymphatic vessels of the upper limb.

medial and posterior to the axillary vein (Fig. 10-21). The afferents of these nodes drain the whole upper limb with the exception of that part whose vessels accompany the cephalic vein. The efferent vessels pass partly to the central and apical groups of axillary nodes, and partly to the inferior deep cervical nodes.

**Pectoral Group.** The pectoral or anterior group of four or five nodes lies along the lateral border of the pectoralis minor muscle, in relationship to the lateral thoracic artery (Fig. 10-21). Their afferent vessels drain the skin and muscles of the anterior and lateral thoracic walls, and the central and lateral parts of the mammary gland; their efferent vessels pass partly to the central and partly to the apical groups of axillary nodes.

**Subscapular Group.** The subscapular or posterior group consists of six or seven axillary nodes placed along the lower margin of the posterior wall of the axilla in the course of the subscapular artery (Fig. 10-21). The afferents of this group drain the skin and muscles of the dorsal part of the neck and the posterior thoracic wall. Their efferents pass to the central group of axillary nodes.

**Central Group.** A central group of three or four large axillary lymph nodes is embedded in the adipose tissue near the base of the axilla (Fig. 10-21). This group of nodes does not drain any specific part of the upper limb directly, but receives vessels from the lateral pectoral and subscapular groups of nodes. Its efferent vessels pass upward and medially to the apical nodes.

**Apical Group.** The apical or **subclavicular group** consists of 6 to 12 axillary lymph nodes situated partly behind the upper part of the pectoralis minor and partly in the apex of the axilla, medial and superior to the upper border of that muscle (Fig. 10-21). Its only direct territorial afferents are those that accompany the cephalic vein, and one or more that drain the upper peripheral part of the mammary gland; however, it receives the efferent vessels from all the other axillary nodes. The efferent vessels of the subclavicular group unite to form the **subclavian trunk**, which opens either directly into the junction of the internal jugular and subclavian veins or into the jugular lymphatic trunk; on the left side it may end in the thoracic duct. A few efferents from the apical nodes usually pass to the inferior deep cervical nodes.

## Lymphatic Vessels and Nodes of the Thorax

In considering the lymphatic drainage of the thorax, initially the lymphatic vessels and then the lymph nodes will be described.

### LYMPHATIC VESSELS OF THE THORAX

The lymphatic vessels of the thorax drain both the thoracic wall and the viscera located within the thoracic cavity.

#### *Lymphatic Vessels of the Thoracic Wall*

The lymphatic vessels of the thoracic wall include the more superficial lymphatic channels that drain the skin and superficial fascia (which on the anterior thoracic wall includes the mammary gland) and the deeper lymphatic vessels that drain the musculature of the thorax, the intercostal spaces, and the diaphragm.

**SUPERFICIAL LYMPHATIC VESSELS OF THE THORACIC WALL.** The superficial lymphatic channels of the thoracic wall ramify beneath the skin and converge on the axillary nodes. These vessels drain the back region superficial to the trapezius and latissimus dorsi muscles, and they course anteriorly and unite to form about 10 or 12 trunks that terminate in the **subscapular group** of axillary

lymph nodes (Fig. 10-21). The vessels that drain the pectoral region, including channels from the skin covering the peripheral part of the mammary gland, course dorsally, but those over the serratus anterior muscle course superiorly, to the **pectoral group** of axillary nodes. Others near the lateral margin of the sternum pass inward, between the rib cartilages, and end in the **parasternal nodes**; the vessels of the two sides anastomose across the anterior surface of the sternum. A few vessels from the upper part of the pectoral region ascend over the clavicle to the supraclavicular group of cervical nodes.

**Lymphatic Vessels of the Mammary Gland.** The lymphatic vessels that drain the mammary gland are numerous and their great clinical importance stems from their role in the spread of malignant cells from carcinoma of the breast. Within the structure of the gland, the lymphatic vessels originate as channels that course along the interlobular spaces and the walls of the lactiferous ducts. Those vessels that drain the glandular tissue and overlying skin of the central part of the breast pass to an intricate plexus situated beneath the areola called the **subareolar plexus** (Fig. 10-21). This plexus also receives lymphatic vessels from the areola, as well as from the nipple.

Efferent collecting vessels from both the superior and inferior aspects of the subareolar plexus course laterally and then superiorly to the **pectoral group** of axillary lymph nodes. Other vessels may bypass the pectoral nodes and course laterally and dorsally to the **subscapular group** of axillary nodes, while a few channels from the superior part of the breast may course to the **apical group** of nodes (Fig. 10-21).

Because most of the lymph draining the breast courses initially to the various groups of axillary nodes, this route is considered the primary direction of drainage. However, some lymphatic vessels from the medial part of the gland are directed medially, pierce the thoracic wall, and end in **parasternal lymph nodes** that course retrosternally with the internal thoracic artery and vein. Some channels communicate directly with the **intercostal nodes**, and other efferent vessels from the lower part of the breast may communicate inferiorly with diaphragmatic and abdominal lymphatic channels, as well as with some from the opposite breast.

FIG. 10-21. Lymphatics of the mammary gland and the axillary nodes. (Poirier and Charpy.)

**DEEP LYMPHATIC VESSELS OF THE THORACIC WALL.** The deep lymphatic vessels of the thoracic wall collect lymph from the deeper tissues of the thoracic cage, including channels from the following three sources: thoracic muscles, intercostal spaces, and the diaphragm.

**Lymphatic Vessels from Thoracic Muscles.** Most of the lymphatic vessels that are derived from muscles attached to the ribs end in the axillary nodes, but some vessels from the medial part of the pectoralis major muscle pass to the parasternal lymph nodes.

**Lymphatic Vessels from Intercostal Spaces.** Lymphatic vessels within the intercostal spaces drain the intercostal muscles and the parietal pleura. Those vessels that drain the external intercostal muscles course dorsally, and after receiving the vessels that accompany the posterior branches of the intercostal arteries, end in the **intercostal nodes** (Fig. 10-22). Those lymphatic vessels that drain the internal intercostal muscles and parietal pleura consist of a single trunk in each space. Coursing ventrally around the intercostal spaces in the subpleural tissue, the upper six trunks open separately into parasternal nodes or into the vessels that unite them. Those of the lower spaces unite

to form a single trunk that terminates in the most caudal of the parasternal nodes.

**Lymphatic Vessels of the Diaphragm.** The lymphatic vessels of the diaphragm form two plexuses, one on its thoracic and another on its abdominal surface. These plexuses anastomose freely with each other, and are most numerous on the parts covered, respectively, by the pleura and peritoneum. On the **thoracic surface** of the diaphragm, the lymphatic vessels communicate with those of the costal and mediastinal parts of the pleura. Their efferents consist of three groups: **anterior**, passing to **anterior diaphragmatic nodes** that lie near the junction of the seventh rib and its cartilage; **middle**, coursing to nodes on the esophagus and to those around the termination of the inferior vena cava; and **posterior**, which terminate in nodes that surround the aorta at the point where this vessel leaves the thoracic cavity. On the **abdominal surface** of the diaphragm, a plexus of fine lymphatic vessels anastomoses with those of the liver, and at the periphery of the diaphragm, with those of the subperitoneal tissue. The efferents from the right half of this plexus terminate partly in a group of nodes on the trunk of the corresponding inferior phrenic artery, while oth-

**Fig. 10-22.** Diagrammatic view of the deep nodes of the thorax and abdomen. Observe the cisterna chyli in the abdomen and the ascending courses of the thoracic duct and the right lymphatic duct.

ers end in the right lateral aortic nodes. Those from the left half of the plexus pass to preaortic and left lateral aortic nodes, and to the nodes on the terminal portion of the esophagus.

#### **Visceral Lymphatic Vessels of the Thorax**

Within the thoracic cavity, visceral plexuses of lymphatic vessels drain the heart, lungs, pleura, thymus, and esophagus.

**LYMPHATIC VESSELS OF THE HEART.** The lymphatic vessels of the heart are arranged in three plexuses, one located deep to the endocardium, one in the myocardium, and one beneath the epicardium (deep to the visceral pericardium). Drainage occurs from deeper lymphatic vessels toward the more superficial surfaces of the heart; thus, the subendocardial vessels drain into the myocardial lymphatics, which, in turn, drain into the subepicardial plexus. Efferent vessels

from the subepicardial plexus form right and left collecting lymphatic trunks. The **left trunks**, two to three in number, ascend in the anterior interventricular sulcus, and receive lymphatic vessels from both ventricles. When they reach the coronary sulcus, they are joined by a large lymphatic trunk that ascends in the posterior interventricular sulcus on the diaphragmatic surface of the heart. The junction of these two lymphatic channels, which primarily drain the left side of the heart, forms a single vessel that ascends between the pulmonary artery and the left atrium and ends in one of the right superior tracheobronchial lymph nodes. The **right trunk** receives its afferents from the right atrium, and from the right border and diaphragmatic surface of the right ventricle. It courses upward in the coronary sulcus, adjacent to the right coronary artery, and then continues its ascent in front of the ascending aorta and terminates in one of the upper left **anterior mediastinal nodes**.

**LYMPHATIC VESSELS OF THE LUNGS.** The lymphatic vessels of the lungs originate in superficial and deep plexuses. The **superficial plexus** is located on the surface of the lung just beneath the pulmonary pleura, while the **deep plexus** accompanies the branches of the pulmonary vessels and the ramifications of the bronchi. In the case of the larger bronchi, the deep plexus consists of a submucous network, located in the walls of the bronchi beneath the mucous membrane, and a peribronchial network found outside the walls of the bronchi. In the smaller bronchi there is only a single plexus, which extends as far as the bronchioles but fails to reach the alveoli, in the walls of which there are no lymphatic vessels. Efferents from the superficial plexus course around the borders of the lungs and along the margins of the fissures separating the lobes. The lymphatics converge to end in **bronchopulmonary nodes** situated at the hilum. Efferents of the deep lymphatics are conducted to the hilum along the pulmonary vessels and bronchi, and end in both **bronchopulmonary** and **tracheobronchial nodes** (Fig. 10-23). Little or no anastomosis occurs between the superficial and deep lymphatics of the lungs, except in the region of the hilum.

**LYMPHATIC VESSELS OF THE PLEURA.** The lymphatic vessels of the pleura consist of channels located in both the visceral and parietal layers. The **visceral set** of lymphat-

ics drains into the superficial efferent vessels of the lungs, deep to the visceral pleura. The **parietal set** of lymphatics has three modes of termination: lymphatics of the *costal pleura* join the lymphatics of the internal intercostal muscles and so reach the **parasternal nodes**; those of the *diaphragmatic pleura* are drained by the efferent vessels on the thoracic surface of the diaphragm (see "Lymphatic Vessels of the Diaphragm"); those of the *mediastinal pleura* terminate in the **posterior mediastinal lymph nodes**.

**LYMPHATIC VESSELS OF THE THYMUS.** The lymphatic vessels of the thymus end in the anterior mediastinal, tracheobronchial, and parasternal nodes.

**LYMPHATIC VESSELS OF THE ESOPHAGUS.** The efferent lymphatic vessels from the cervical part of the esophagus drain into **paratracheal** and **deep cervical nodes**; those from the thoracic part end in **posterior mediastinal nodes**; and those from the abdominal part drain into the **left gastric lymph nodes**.

## LYMPH NODES OF THE THORAX

The lymph nodes of the thorax are divided into nodes that drain the thoracic wall and those that drain the thoracic viscera.

### *Lymph Nodes of the Thoracic Wall*

The lymph nodes of the thoracic wall drain the soft and hard tissues of the thoracic cage, and are at times referred to as the **parietal nodes** of the thorax. They include the following:

- Parasternal nodes
- Intercostal nodes
- Diaphragmatic nodes

**PARASTERNAL NODES.** The parasternal lymph nodes are located at the anterior ends of the intercostal spaces, and form a longitudinal chain of four to six nodes along the course of the internal thoracic artery. These important nodes derive afferent vessels from the mammary gland, from the deeper structures of the anterior abdominal wall above the level of the umbilicus, from the diaphragmatic surface of the liver through a small group of nodes that lies behind the xiphoid process, and from the deeper parts of the anterior thoracic wall. Their efferent

vessels usually unite to form a single trunk on each side of the sternum. This trunk may open directly into the junction of the subclavian and internal jugular veins, or, on the right side, it may join the main lymphatic duct on the subclavian duct, and on the left side, the thoracic duct. At times it may join lymphatic vessels from the tracheobronchial and anterior mediastinal nodes to form the **bronchomediastinal trunk**, which then enters the venous system either directly or through the large lymphatic ducts at the root of the neck.

**INTERCOSTAL NODES.** The intercostal lymph nodes are located in the dorsal part of the thorax, within the intercostal spaces near the heads of the ribs (Fig. 10-22). There are one or more in each interspace and they lie in relationship to the intercostal vessels. The intercostal lymph nodes receive the deep lymphatics from the posterolateral aspect of the chest, as well as from certain channels from the breast; some of these vessels are interrupted by small lateral intercostal nodes. The efferent vessels of the nodes in the lower four or five spaces unite to form a trunk that descends and opens either into the cisterna chyli or into the commencement of the thoracic duct. The efferent channels of the nodes in the upper spaces of the left side end in the thoracic duct, and those of the corresponding right spaces, in the right lymphatic duct.

**DIAPHRAGMATIC NODES.** The diaphragmatic nodes lie on the thoracic aspect of the diaphragm and consist of three sets: anterior, lateral, and posterior.

**Anterior Diaphragmatic Nodes.** The anterior diaphragmatic set consists of two or three small nodes, located dorsal to the base of the xiphoid process, that receive afferents from the convex surface of the liver, and one or two nodes, located on each side near the junction of the seventh rib with its cartilage, that receive lymphatic vessels from the anterior part of the diaphragm. The efferent vessels of the anterior set pass to the **parasternal nodes**.

**Lateral Diaphragmatic Nodes.** The lateral diaphragmatic set consists of two or three small nodes on each side, close to the site where the phrenic nerves enter the diaphragm. On the right side, some of the nodes of this group lie within the fibrous sac of the pericardium, anterior to the termination of the inferior vena cava; on the left side, they

extend to the esophageal hiatus. The afferent vessels of the lateral diaphragmatic nodes are derived from the middle region of the diaphragm; those on the right side also receive afferents from the convex surface of the liver. Their efferents pass to the **parasternal nodes** by way of the anterior diaphragmatic nodes, to the upper **anterior mediastinal nodes** by a vessel that courses superiorly with the phrenic nerve, and to the **posterior mediastinal nodes**.

**Posterior Diaphragmatic Nodes.** The posterior diaphragmatic set consists of a few nodes situated on the back of the crura of the diaphragm, and communicates on the one hand with the lateral aortic set of lumbar nodes, and on the other with the posterior mediastinal nodes.

### *Lymph Nodes of the Thoracic Viscera*

Lymphatic vessels that drain the organs of the thorax pass initially through groups of **visceral nodes**. Usually three groups are described:

Anterior mediastinal  
Posterior mediastinal  
Tracheobronchial

**ANTERIOR MEDIASTINAL NODES.** The anterior mediastinal nodes are located in the anterior part of the superior mediastinum, in front of the brachiocephalic veins, the aortic arch, and the large arterial trunks that arise from the aorta (Fig. 10-22). They receive afferent lymphatic vessels from the thymus, heart, and pericardium, and from the lower end of the thyroid gland. Additionally, the anterior mediastinal nodes receive lymph from the mediastinal pleura and anterior part of the hilus of the lung, from the parasternal nodes, and from the diaphragm and liver by way of the lateral diaphragmatic nodes. Their efferent vessels unite with those of the tracheobronchial nodes to form the **right and left bronchomediastinal trunks**, which ascend in the thorax to open into the main lymphatic ducts or into the venous system directly in the root of the neck.

**POSTERIOR MEDIASTINAL NODES.** The posterior mediastinal nodes lie behind the pericardium in relationship to the esophagus and descending thoracic aorta. There are eight to ten nodes in this group, and their

afferent vessels are derived from the esophagus, the posterior part of the pericardium, the diaphragm, and the convex surface of the liver. Their efferent channels mostly end in the **thoracic duct**, but some join the **tracheobronchial nodes**.

**TRACHEOBRONCHIAL NODES.** The tracheobronchial nodes are assembled in five groups:

- Tracheal
- Superior tracheobronchial
- Inferior tracheobronchial
- Bronchopulmonary
- Pulmonary

**Tracheal Nodes.** The tracheal nodes extend along both sides of the thoracic part of the trachea, and are therefore sometimes called the **paratracheal nodes** (Fig. 10-23).

**Superior Tracheobronchial Nodes.** The superior tracheobronchial nodes are found

on each side, superior and lateral to the angle at which the trachea bifurcates into the two primary bronchi. The chains continue laterally along the superior border of the two principal bronchi (Fig. 10-28).

**Inferior Tracheobronchial Nodes.** The inferior tracheobronchial nodes lie in the angle below the bifurcation of the trachea, and their chains continue inferolaterally along the lower border of the principal bronchi (Fig. 10-23).

**Bronchopulmonary Nodes.** The bronchopulmonary nodes are found at the hilus of each lung, at the site of division of the principal bronchi and pulmonary vessels into the lobar bronchi and vessels (Fig. 10-23).

**Pulmonary Nodes.** The pulmonary lymph nodes are found in the lung substance along the course of the segmental bronchi.

The tracheal nodes in the thorax receive afferent vessels that drain the trachea and

**FIG. 10-23.** Posterior view of the deep visceral nodes of the thorax. Note the right and left superior and inferior tracheobronchial nodes. The superior nodes of these groups lie above the tracheobronchial angle on each side, while the inferior tracheobronchial nodes are located below the angle of division of the trachea into the two primary bronchi. (After Hallé.)

the upper thoracic portion of the esophagus. The remaining groups of tracheobronchial nodes form continuous chains, and it is difficult to define the limits of each group. Certainly, however, the superficial and deep lymphatics of the lungs and the bronchial trees drain into the pulmonary and bronchopulmonary nodes, which, in turn, drain into the superior and inferior tracheobronchial nodes. The latter also receive some afferent vessels from other posterior mediastinal organs.

The efferent vessels from the tracheobronchial nodes ascend with those of the tracheal nodes, which unite with efferents of the parasternal and anterior mediastinal nodes to form the **right and left bronchomediastinal trunks**. The right bronchomediastinal trunk may join the right lymphatic duct, and the left may join the thoracic duct. More frequently, however, they open independently of these ducts into the junction of the internal jugular and subclavian veins of their own side.

**CLINICAL NOTE.** There are continually being swept into the bronchi and alveoli of all city dwellers large quantities of inhaled dust and black carbonaceous pigment. Particles that are not picked up by dust cells, caught in the mucus, and discharged are taken up by phagocytes and transported in the lymphatic vessels to the lymph nodes. This results in an enlargement and a blackened coloration of the lymph nodes in the tracheobronchial groups. The work environment can markedly enhance this condition. The lymph nodes and lungs of coal miners invariably contain large amounts of entrapped black particles (anthracosis). Other types of dust particles may also be inhaled chronically as a result of occupational activities and entrapped in these lymph nodes. Thus, the lungs of iron workers show deposits of iron particles (siderosis), and those of stone masons show stone dust or sand (silicosis).

## Lymphatic Vessels and Nodes of the Abdomen and Pelvis

In describing the lymphatic vessels and nodes of the abdomen and pelvis, initially the lymphatic vessels and then the lymph nodes will be considered.

### LYMPHATIC VESSELS OF THE ABDOMEN AND PELVIS

The lymphatic vessels of the abdomen and pelvis include the *parietal* channels that drain the abdominal and pelvic walls, and the *visceral* vessels of the abdominal and pelvic organs.

#### *Lymphatic Vessels of the Abdominal and Pelvic Wall*

Both superficial and deep lymphatic vessels drain the walls of the abdomen and pelvis. Together they constitute the *parietal* vessels of these regions of the trunk.

**SUPERFICIAL LYMPHATIC VESSELS OF THE ABDOMINAL AND PELVIC WALLS.** The lymphatic vessels in the skin and superficial fascia of the anterior abdominal wall above the umbilicus drain upward, into the superficial collecting channels of the anterior thoracic wall and therefore into the **axillary nodes**. Below the umbilicus, the superficial lymphatic vessels follow the course of the superficial blood vessels and converge to the **superficial inguinal nodes**. Lymphatic channels from the superficial tissue overlying the rectus abdominis muscle follow the course of the superficial epigastric vessels; those from the lateral regions of the abdominal wall pass along the crest of the ilium with the superficial iliac circumflex vessels. The superficial lymphatic vessels of the gluteal region turn horizontally around the buttock, and join the upper and lower groups of superficial inguinal lymph nodes.

**DEEP LYMPHATIC VESSELS OF THE ABDOMINAL AND PELVIC WALLS.** The deep lymphatic vessels of the abdominal and pelvic walls also accompany the principal blood vessels. Those of the parietes of the pelvis accompany the branches of the internal iliac artery and drain into the **internal iliac** and **common iliac nodes**, and eventually into the *lateral aortic* group of **lumbar lymph nodes** on each side (Figs. 10-24; 10-34 to 10-36).

#### *Lymphatic Vessels of the Abdominal and Pelvic Viscera*

The visceral lymphatic vessels of the abdomen and pelvis include the lymphatic channels of the:

**FIG. 10-24.** The parietal lymph nodes of the pelvis. (Cunéo and Marcille.)

Subdiaphragmatic portion of the digestive tube and its associated glands  
 Spleen and suprarenal glands  
 Urinary tract  
 Reproductive organs  
 Perineum and external genitalia

**LYMPHATIC VESSELS FROM THE SUBDIAPHRAGMATIC PORTION OF THE DIGESTIVE TUBE AND ITS ASSOCIATED GLANDS**

The lymphatic vessels of the digestive tube below the level of the diaphragm are situated partly in the mucosa and partly in the submucosal, muscular, and serosal coats. Because the vessels in the mucosa drain into the deeper layers, the lymphatics will be considered as a single system in any part of

the gastrointestinal tube. The following regional visceral lymphatics will be described:

Stomach  
 Duodenum  
 Greater omentum  
 Jejunum and ileum  
 Appendix and cecum  
 Colon  
 Rectum and anal canal  
 Liver  
 Gallbladder  
 Pancreas

**LYMPHATIC VESSELS OF THE STOMACH.** The lymphatic vessels of the stomach are continuous at the cardiac orifice with those of the esophagus, and at the pylorus with those of the duodenum (Figs. 10-25; 10-26). They

mainly follow the blood vessels and are arranged in four sets. Lymphatic vessels of the first set accompany the branches of the left gastric artery, receive tributaries from a large area on both anterior and posterior surfaces of the stomach, and terminate in the **left gastric lymph nodes**. Lymphatic channels of the second set drain the fundus and body of the stomach to the left of a line drawn vertically from the esophagus. They accompany, more or less closely, the short gastric and left gastroepiploic arteries and end in the **pancreaticosplenic lymph nodes**. The vessels of the third set drain the right portion of the greater curvature of the stomach as far as the pylorus, and end in the **right gastroepiploic nodes**, the efferents of which pass to the **pyloric nodes**. Lymphatic vessels of the fourth set drain the pyloric portion and pass to the **hepatic, pyloric, and left gastric lymph nodes** (Figs. 10-25; 10-26).

**LYMPHATIC VESSELS OF THE DUODENUM.** The lymphatic vessels of the duodenum consist of anterior and posterior sets that open into a series of small **pyloric nodes**, located on the anterior and posterior aspects of the groove between the head of the pancreas and the duodenum (Figs. 10-25; 10-26). The efferents of these nodes course in two direc-

tions, superiorly to the **hepatic nodes** and inferiorly to the **preaortic group of lumbar nodes**, around the origin of the superior mesenteric artery.

**LYMPHATIC VESSELS OF THE GREATER OMENTUM.** The lymphatic vessels of the greater omentum course longitudinally with the omental blood vessels that branch from the right and left gastroepiploic arteries and veins. The lymphatic channels ascend to empty into lymphatic vessels and nodes along the greater curvature of the stomach. On the right side these drain into the **right gastroepiploic and pyloric nodes**, but on the left side they drain into the **pancreaticosplenic nodes**.

**LYMPHATIC VESSELS OF THE JEJUNUM AND ILEUM.** The lymphatic vessels of the jejunal and ileal regions of the small intestine are termed **lacteals** because of the milk-white lymph they contain during intestinal digestion after a fatty meal. They course between the layers of the mesentery and enter the **mesenteric nodes**, the efferents of which end in the **superior mesenteric set of preaortic nodes**.

**LYMPHATIC VESSELS OF THE APPENDIX AND CECUM.** The ileocolic, appendicular, and cecal regions of the gastrointestinal tract

**FIG. 10-25.** Lymphatic vessels and nodes of the stomach. (Redrawn after Jamieson and Dobson, 1907.)

**Fig. 10-26.** The lymphatic vessels of the stomach, duodenum, and pancreas demonstrated with the stomach turned upward. (After Jamieson and Dobson, 1907b.)

contain many lymphatic vessels because there is much lymphoid tissue in the walls of these parts of the gastrointestinal tract. From the body and tail of the vermiform appendix, 8 to 15 vessels ascend between the layers of the mesentery of the appendix, several being interrupted by the small (appendicular) nodes that lie between the peritoneal layers. These vessels unite to form three or four channels that end partly in the lower and partly in the upper nodes of the ileocolic chain (Figs. 10-27; 10-28). The vessels from the root of the appendix and from the cecum form anterior and posterior groups. The anterior vessels pass in front of the cecum, and end in the **anterior ileocolic nodes** and in the upper and lower nodes of the ileocolic chain (Fig. 10-27). The posterior vessels ascend over the dorsal aspect of the cecum, and terminate in the **posterior ileocolic nodes** and in the lower nodes of the ileocolic chain (Fig. 10-28).

**LYMPHATIC VESSELS OF THE COLON.** The lymphatic vessels of the ascending and transverse colon drain through nodes located along the course of the marginal artery (paracolic nodes), as well as through the **right colic** and **middle colic nodes**, on their way to the **superior mesenteric set of pre-aortic nodes** (Fig. 10-29). Those of the descending and sigmoid parts of the colon are interrupted by the small nodes on the branches of the left colic and sigmoid arteries, and ultimately end in the **inferior mesenteric set of preaortic nodes**.

**LYMPHATIC VESSELS OF THE RECTUM AND ANAL CANAL.** The lymphatic vessels of the rectum have important clinical significance because of the high incidence of carcinoma in this lower region of the large intestine. As in other parts of the intestinal tract, the rectum contains both submucosal and muscular networks of lymphatic vessels. The *mucocutaneous* or *pectinate line* forms a boundary

**FIG. 10-27.** The lymphatics of cecum and vermiform appendix from the front. (Jamieson and Dobson, 1907a.)

**FIG. 10-28.** The lymphatics of cecum and vermiform appendix from behind. (Jamieson and Dobson, 1907a.)

Fig. 10-29. Lymphatic vessels and nodes of the large intestine. (After Jamieson and Dobson, 1909.)

between those lymphatics above, which drain into pelvic and lower abdominal nodes, and those lymphatics below, which drain outside the pelvis and with the perineal lymphatics to the superficial inguinal nodes. The lymphatic vessels of the rectum can be divided into superior, middle, and inferior channels.

The superior lymphatics of the rectum join those of the sigmoid colon and drain initially through **pararectal nodes**, which lie parallel to the rectum, and then superiorly along the course of the superior rectal artery and vein, to end in the **inferior mesenteric group of preaortic nodes**. The middle group of lymphatics drains approximately 10 cm of rectum above the mucocutaneous line. These channels run downward, along the course of the inferior rectal blood vessels, and terminate in nodes that accompany their branches; laterally, along the course of the middle rectal artery and vein, to terminate in

the **internal iliac nodes**; and superiorly, to join the uppermost channels of the rectum. The inferior group of rectal lymphatics drains the anal canal distal to the mucocutaneous line. These vessels descend to the skin and superficial fascia of the perineum, and course to the **superficial inguinal nodes**. From these nodes lymphatic vessels enter the pelvis by way of the external and common iliac nodes.

**LYMPHATIC VESSELS OF THE LIVER.** The lymphatic vessels of the liver are divisible into two sets, superficial and deep.

**Superficial Lymphatic Vessels.** The superficial lymphatic vessels of the liver course beneath the peritoneum and over the entire surface of the organ; they may be grouped into those located on the convex **diaphragmatic surface** and those on the **visceral surface**.

**Diaphragmatic Surface.** The dorsal part of the diaphragmatic surface of the liver is

drained by lymphatic vessels on its right, middle, and left aspects. One or two vessels along the right side course backward on the abdominal surface of the diaphragm, and after crossing the right crus, they end in the **celiac group of preaortic nodes**. Five or six channels along the middle part of the diaphragmatic surface pass through the vena caval foramen in the diaphragm, and end in one or two lymph nodes that are situated around the terminal part of the inferior vena cava. A few lymphatic vessels from the left side pass dorsally, toward the esophageal hiatus, and terminate in the **paracardial group of left gastric nodes**.

From the ventral part of the diaphragmatic surface of the right and left lobes adjacent to the falciform ligament, the lymphatic vessels converge to form two trunks. One of these accompanies the inferior vena cava through the diaphragm and ends in the nodes around the terminal part of this vessel, while the other courses downward and anteriorly, and turning around the inferior sharp margin of the liver, accompanies the upper part of the ligamentum teres to end in the **hepatic nodes**. A few additional vessels from this anterior surface also turn around the inferior sharp margin to reach the hepatic nodes.

**Visceral Surface.** The lymphatic vessels from the visceral surface of the liver mostly converge toward the porta hepatis. They accompany the deep lymphatics that emerge from the liver at this site, and end in the **hepatic nodes**. One or two channels from the posterior parts of the right and caudate lobes accompany the inferior vena cava through the diaphragm and end in nodes near the termination of this vein.

**Deep Lymphatic Vessels.** The deep lymphatic vessels from the internal substance of the liver join to form ascending and descending trunks. The ascending trunks accompany the hepatic veins and pass through the diaphragm, to end in lymph nodes around the terminal part of the vein. The descending trunks emerge from the porta hepatis and end in the **hepatic nodes**.

**LYMPHATIC VESSELS OF THE GALLBLADDER.** The lymphatic vessels that drain the gallbladder pass to the **hepatic nodes** in the porta hepatis. There is evidence that interconnections exist between lymphatic channels of the gallbladder and the liver, which possibly helps to explain the spread of infec-

tions and other diseases between these two organs. Lymphatic vessels of the **common bile duct** course to the **hepatic nodes**, alongside the duct, and to the upper **pancreaticoduodenal nodes**.

**LYMPHATIC VESSELS OF THE PANCREAS.** The lymphatic vessels of the pancreas follow the course of its blood vessels (Fig. 10-26). Most of them enter the **pancreaticosplenic nodes**, but some end in nodes located along the pancreaticoduodenal vessels. Other pancreatic lymphatic channels open into the **superior mesenteric set of preaortic nodes**.

#### LYMPHATIC VESSELS FROM THE SPLEEN AND SUPRARENAL GLANDS

**LYMPHATIC VESSELS OF THE SPLEEN.** The lymphatic vessels of the spleen are principally derived from the capsule and from the connective tissue that forms the trabeculae. These pass to **splenic nodes**, located between the layers of the gastrosplenic ligament at the hilus, and to **pancreaticosplenic nodes**, located along the superior border of the tail of the pancreas (Fig. 10-25).

**LYMPHATIC VESSELS OF THE SUPRARENAL GLANDS.** The lymphatic vessels of the suprarenal glands usually accompany the suprarenal veins and end in the **lateral aortic set of lumbar nodes**. Occasionally some vessels pierce the crura of the diaphragm and end in the **posterior mediastinal nodes**.

#### LYMPHATIC VESSELS OF THE URINARY TRACT

**LYMPHATIC VESSELS OF THE KIDNEY.** The lymphatic vessels of the kidney form three plexuses: one in the substance of the renal cortex, a second beneath the fibrous capsule of the kidney, and a third in the perinephric fat.

The subcapsular and perinephric plexuses communicate freely with each other. The lymphatic vessels from the plexus in the substance of the kidney converge to form four or five trunks that emerge at the hilus. Here they are joined by vessels from the subcapsular plexus, and following the course of the renal vein, they end in the **lateral aortic set of lumbar nodes**. The perinephric plexus drains directly into the more superior of the **lateral aortic nodes**.

**LYMPHATIC VESSELS OF THE URETER.** The lymphatic vessels of the ureter commence in

plexuses within the muscular and adventitial layers of the organ. The channels from the proximal portion end partly in the efferent vessels of the kidney, and in part directly in the **lateral aortic set of lumbar nodes**. Those from the middle portion (above the pelvic brim) drain into **common iliac nodes**, whereas the vessels from the intrapelvic portion of the tube (below the pelvic brim) drain into **external and internal iliac nodes**, and more distally may join efferent vessels from the bladder.

**LYMPHATIC VESSELS OF THE BLADDER.** The lymphatic vessels of the bladder commence in muscular and extramuscular plexuses, and it is claimed that the mucous membrane is devoid of lymphatic channels. The efferent vessels emerge from the bladder in three groups: those from the anterior aspect, the

posterior aspect, and the region of the trigone.

The vessels from the anterior part of the inferolateral surface and the anterior part of the superior surface pass laterally along the course of the obliterated umbilical artery and end in the **external iliac nodes** (Fig. 10-30). Located along their course are minute nodes that are arranged in front of the bladder in an **anterior vesical group**, and a **lateral vesical group**, adjacent to the lateral umbilical ligament.

Most of the vessels from the posterior part of the inferolateral surface pass laterally and backward to **common iliac and internal iliac nodes**, but a few vessels course backward, even beyond the bifurcation of the aorta, to one or two nodes in front of the sacral promontory (Fig. 10-30). The channels from the

Fig. 10-30. Lymphatic vessels from the bladder.

posterior part of the superior surface also course laterally to the **common iliac and internal iliac nodes**.

Lymphatic vessels from the trigone of the bladder course upward and laterally to both the **external and internal iliac nodes**.

**LYMPHATIC VESSELS OF THE URETHRA.** The lymphatic vessels of nearly the entire female urethra and of the prostatic and membranous parts of the male urethra pass principally to the **internal iliac lymph nodes**. Lymphatics from the distal extremity of the female urethra drain with those from the skin of the female external genitalia to the superficial inguinal nodes.

Lymphatic vessels from the spongy portion of the male urethra accompany those of the glans penis and terminate in the **deep inguinal nodes**, adjacent to the femoral artery. Other vessels course upward along the inguinal canal and drain into the **external iliac nodes**.

#### LYMPHATIC VESSELS OF THE MALE REPRODUCTIVE ORGANS

**LYMPHATIC VESSELS OF THE TESTIS.** The lymphatic vessels of the testis consist of two sets, superficial and deep. The **superficial vessels** commence on the surface of the tunica vaginalis, while the **deep vessels** are derived from the epididymis and body of the testis. They form four to eight collecting trunks that ascend with the testicular blood vessels in the spermatic cord. At the abdominal inguinal ring, they continue upward on the anterior surface of the psoas major muscle to the point where the testicular artery and vein cross the ureter, and they end in the **lateral and preaortic sets of lumbar nodes**.

**LYMPHATIC VESSELS OF THE DUCTUS DEFERENS AND SEMINAL VESICLES.** Only superficial lymphatic vessels that drain the ductus deferens have been described, and these terminate in the **external iliac nodes**.

Both superficial and deep lymphatic vessels drain the seminal vesicles, and these drain into the **external iliac and internal iliac lymph nodes** (Fig. 10-31).

**LYMPHATIC VESSELS OF THE PROSTATE.** The lymphatic vessels of the prostate gland terminate principally in the **internal iliac and sacral lymph nodes** (Fig. 10-31). One lymph vessel from the posterior surface of the prostate, however, courses laterally and ends in

the **external iliac nodes**, while another from the anterior surface of the gland joins the vessels that drain the membranous part of the urethra and terminates in the **internal iliac nodes**.

#### LYMPHATIC VESSELS OF THE FEMALE REPRODUCTIVE ORGANS

**LYMPHATIC VESSELS OF THE OVARY.** A rich plexus of lymphatic vessels drains each ovary, and when they leave the hilum, they follow the course of the ovarian artery and vein to terminate in the **lateral and preaortic sets of the lumbar nodes**.

**LYMPHATIC VESSELS OF THE UTERINE TUBI**  
The lymphatic vessels of the upper and middle parts of the uterine tube follow those from the ovary and end in the **lateral and preaortic sets of lumbar nodes**. Channels that drain the lowest part of the uterine tube course laterally between the leaves of the broad ligament to the **internal iliac nodes**, and with the round ligament, through the inguinal canal to the **superficial inguinal nodes**.

**LYMPHATIC VESSELS OF THE UTERUS.** The lymphatic vessels of the uterus consist of two sets, **superficial** and **deep**, the former placed beneath the peritoneum, the latter in the wall of the uterus.

Efferent vessels from the **cervix of the uterus** course in three directions: *laterally* with the uterine artery to the **external iliac nodes**; *posterolaterally*, passing behind the ureter, to the **internal iliac nodes**; and *posteriorly*, to the **common iliac and lateral sacral nodes** (Figs. 10-32; 10-33).

The majority of the lymphatic vessels of the **body and fundus of the uterus** pass laterally in the broad ligaments with the uterine artery to **internal iliac nodes**. Others are continued superiorly with the ovarian vessels and end in the **lateral and preaortic sets of lumbar nodes**. A few channels course to the **external iliac nodes**, and one or two vessels traverse the inguinal canal and end in the **superficial inguinal nodes**. In the nongravid uterus, the lymphatic vessels are very small, but during gestation they are greatly enlarged.

**LYMPHATIC VESSELS OF THE VAGINA.** Three groups of lymphatic vessels drain the vagina (Fig. 10-33). The **upper** (cervicovaginal) channels course laterally with branches of

**FIG. 10-31.** Lymphatic vessels of the prostate and middle rectal region.

the uterine artery to the **external and internal iliac nodes**. Lymphatic vessels from the middle region of the vagina follow the branches of the vaginal artery to the **internal iliac nodes**, along the course of which are interspersed other minute nodes. Some lymphatic vessels from the lower part of the vagina join those of the middle portion and course toward nodes in the lateral wall of the pelvis, while others near the vaginal orifice join those of the vulva and pass to the **superficial inguinal nodes**. The lymphatics of the vagina interconnect with those of the cervix of the uterus, the rectum, and the external genitalia, but not with those of the bladder.

#### LYMPHATIC VESSELS OF THE PERINEUM AND EXTERNAL GENITALIA

**LYMPHATIC VESSELS OF THE UROGENITAL REGION.** The lymphatic vessels of the skin and superficial fascia in the urogenital region of the perineum, along with the superficial lymphatic vessels from the skin of the scrotum and penis and those of the labia majora and labia minora, course laterally with the external pudendal artery and vein and terminate in the **upper and lower superficial inguinal nodes**.

The lymphatic vessels of the glans penis and clitoris course with the deep dorsal vein and drain laterally to the deep inguinal

**FIG. 10-32.** Lymphatic vessels draining the uterus.

nodes (Fig. 10-34). These vessels may extend superiorly, even through the femoral canal, to the **external iliac nodes**. Other channels course upward through the inguinal canal also to achieve the **external iliac nodes**.

**LYMPHATIC VESSELS OF THE ANAL REGION.** The superficial lymphatic vessels in the **anal** region of the perineum also course to the **superficial inguinal lymph nodes**. Some channels, those deeper in the ischiorectal fossa, follow the course of the inferior rectal and internal pudendal blood vessels and thereby enter the pelvis and end in the **internal iliac nodes**.

#### **LYMPH NODES OF THE ABDOMEN AND PELVIS**

The lymph nodes of the abdomen and pelvis may be divided, according to their location, into those nodes that lie behind the

peritoneum, adjacent to the **walls** of the abdominopelvic cavity in close association with the large blood vessels, and those lymph nodes that are more intimately related to the abdominopelvic **viscera** and to the vessels more directly supplying the organs.

#### **Lymph Nodes of the Abdominal and Pelvic Walls**

The lymph nodes located adjacent to the walls of the abdominal and pelvic cavities are frequently referred to as **parietal nodes**. These nodes include the following groups:

- External iliac
- Common iliac
- Epigastric
- Circumflex iliac
- Internal iliac

**Fig. 10-33.** Lymphatic vessels of the vagina and uterus.

Sacral  
Lumbar  
Lateral aortic  
Preaortic  
Retroaortic

**EXTERNAL ILIAC NODES.** The external iliac nodes, eight to ten in number, lie along the external iliac vessels (Figs. 10-24; 10-35; 10-36). They are arranged in three groups, one on the lateral aspect, another on the medial aspect, and a third, which is sometimes absent, on the anterior aspect of the vessels. The external iliac nodes receive afferent vessels from:

(a) the lower extremity, by way of the superficial and deep inguinal nodes, as well as from some lymphatics from the adductor region of the thigh;

(b) the lower anterior abdominal wall, by way of the epigastric and circumflex iliac nodes;

(c) the perineum, by way of lymphatic channels from the glans penis or clitoris that reach the external iliac nodes through the inguinal canal, and by means of vessels that course laterally from the genitalia and then superiorly through the femoral canal;

(d) the pelvis, through direct channels from the fundus of the bladder, the prostate,

FIG. 10-34. Lymphatic vessels draining the glans penis and the spongy and membranous portions of the urethra.

and membranous urethra in the male, or from the upper vagina and uterine cervix in the female.

Efferent vessels leave the external iliac nodes and ascend to common iliac and lumbar nodes.

**COMMON ILIAC NODES.** The six to eight common iliac nodes are located medial, lateral, and posterior to the common iliac vessels (Figs. 10-24; 10-35; 10-36), and they extend from the external iliac nodes to the bifurcation of the aorta. Several of the **medial nodes** are located in front of the fifth lumbar vertebra and the promontory of the sacrum; these extend downward from the bifurcation of the aorta. The **lateral and posterior nodes** directly extend the chain of parietal pelvic nodes from the external and internal iliac sets to the lateral lumbar nodes.

**EPIGASTRIC NODES.** Three or four epigastric nodes follow the course of the lower part of the inferior epigastric vessels, and their efferent channels drain into the external iliac nodes.

**CIRCUMFLEX ILIAC NODES.** Two to four cir-

cumflex iliac nodes, when present, are situated along the course of the deep circumflex iliac vessels. Their efferent channels also drain into the external iliac nodes.

**INTERNAL ILIAC NODES.** The internal iliac nodes surround the internal iliac vessels, and they receive lymphatics that correspond to the distribution of the branches of the internal iliac artery (Figs. 10-30; 10-32 to 10-36). Lying deep to the pelvic fascia, they receive lymphatics from all the pelvic viscera, from the deeper parts of the perineum, including the membranous and spongy portions of the urethra, and from the gluteal region and dorsum of the thigh. An **obturator node** is sometimes seen in the upper part of the obturator foramen. The efferent vessels of the internal iliac group end in the common iliac nodes.

**SACRAL NODES.** Five or six sacral nodes lie in the cavity of the sacrum, in relationship to the median and lateral sacral arteries (Figs. 10-30 to 10-32; 10-34). They receive lymphatics from the rectum and posterior wall of the pelvis, and pass to the internal iliac and lumbar nodes.

**Fig. 10-35.** Lymphatic nodes of the pelvis and posterior abdominal wall. (From Rouvier, H., *Anatomie Humaine*, 7th ed., Masson, Paris, 1954.)

**LUMBAR NODES.** The lumbar nodes are numerous and consist of right and left lateral aortic, preaortic, and retroaortic groups.

**Right and Left Lateral Aortic Nodes.** The right lateral aortic nodes are situated partly anterior to the inferior vena cava, near the termination of the renal vein, and partly posterior to it on the origin of the psoas major muscle, and on the right crus of the diaphragm. The left lateral aortic nodes form a chain on the left side of the abdominal aorta, in front of the origin of the psoas major and left crus of the diaphragm (Figs. 10-22; 10-24; 10-30; 10-31; 10-35; 10-36).

On both sides of the midline, the lateral aortic nodes receive lymphatic vessels from the common iliac nodes; from the testis in the male or from the ovary, uterine tube, and body of the uterus in the female; from the kidney and suprarenal glands; and from lymphatics draining the lateral abdominal muscles and accompanying the lumbar veins. Most of the efferent vessels of the lateral aortic nodes converge to form the **right**

and **left lumbar trunks**, which join the cisterna chyli, but some enter the preaortic and retroaortic nodes, and others pierce the crura of the diaphragm to join the lower end of the thoracic duct.

**Preaortic Nodes.** The preaortic nodes are divided into **celiac**, **superior mesenteric**, and **inferior mesenteric** groups, arranged around the origins of the corresponding arteries (Figs. 10-22; 10-33; 10-35; 10-36). They receive a few vessels from the lateral aortic nodes, but their principal afferent vessels are derived from the viscera supplied by the three arteries with which they are associated. Some of their efferent vessels pass to the retroaortic nodes, but the majority unite to form the **intestinal trunk**, which enters the cisterna chyli.

**Retroaortic Nodes.** The retroaortic nodes are placed below the cisterna chyli on the bodies of the third and fourth lumbar vertebrae. They receive lymphatic trunks from the lateral and preaortic nodes, and their efferent vessels end in the cisterna chyli.

**FIG. 10-36.** Lymphadenogram showing the parietal lymph nodes of the pelvis and of the posterior abdominal wall. 1, External iliac nodes; 2, internal iliac nodes; 3, common iliac nodes; 4, lateral aortic (lumbar) nodes; 5, preaortic (lumbar) nodes. (From Gooneratne, B. W. M., *Lymphography—Clinical and Experimental*, Butterworth and Co. Ltd., London, 1974.)

### ***Lymph Nodes of the Abdominal Organs***

The lymph nodes of the abdominal organs are frequently referred to as the **visceral nodes** of the abdomen. They are closely associated with the blood vessels, either being clustered in groups at the origin of the ves-

sels, or forming chains along the courses of their branches. The three principal groups of nodes into which lymph from most of the abdominal visceral nodes eventually drains before entering the cisterna chyli or the thoracic duct are the **celiac**, **superior mesenteric**, and **inferior mesenteric** sets of

preaortic nodes. These surround the roots of the large and similarly named unpaired arteries, allowing convenient classification of the outlying chains of nodes along branches or subbranches of these vessels (Fig. 10-22).

### CELIAC NODES

The celiac nodes include those nodes that drain the stomach, greater omentum, liver, gallbladder, and spleen, and most but not all of the lymph from the pancreas and duodenum. The celiac nodes are divided into the following sets:

- Left gastric
- Right gastric
- Hepatic
- Pyloric
- Pancreaticosplenic

**LEFT GASTRIC NODES.** The left gastric nodes follow the course of the left gastric artery and consist of the following three groups: upper, lower, and paracardial (Figs. 10-25; 10-26). The **upper left gastric nodes** lie at the root of the left gastric artery, where it branches from the celiac trunk. The **lower left gastric nodes** accompany the descending branches of the artery along the cardiac half of the lesser curvature of the stomach, between the two layers of the lesser omentum. The **paracardial** group of celiac nodes is located around the cardiac end of the stomach in a radial manner, comparable to a chain of beads. The left gastric nodes receive afferent vessels from the stomach, and their efferent channels pass to the **celiac group of preaortic nodes**.

**RIGHT GASTRIC NODES.** The right gastric nodes lie between the leaves of the lesser omentum, along the course of the right gastric artery. They drain the lower end of the lesser curvature and their efferent vessels pass to the **hepatic nodes** (Figs. 10-25; 10-26).

**HEPATIC NODES.** The hepatic nodes are located between the two layers of the lesser omentum and course along the common hepatic artery and its right and left hepatic branches as far as the porta hepatis (Fig. 10-25). One node of this group is placed near the neck of the gallbladder and is known as the **cystic node**. A few additional nodes descend along the common bile duct as far as the head of the pancreas. The nodes of the hepatic chain receive afferent vessels from the stomach, duodenum, liver, gallbladder, the

bile ducts, and pancreas. Their efferent channels join the **celiac group of preaortic nodes**.

**PYLORIC NODES.** The pyloric nodes lie adjacent to the head of the pancreas and along the medial border of the superior end of the descending part of the duodenum (Figs. 10-25; 10-26). They are located in close relationship to the pylorus of the stomach, and at the site of bifurcation of the gastroduodenal artery. They receive afferent vessels from the pylorus of the stomach, the superior part of the duodenum, as well as from the **right gastroepiploic nodes**, which course between the layers of the greater omentum, along the greater curvature of the stomach with the right gastroepiploic artery (Fig. 10-25). Their efferent channels drain to the **hepatic nodes** and the **celiac group of preaortic nodes**, as well as to the **superior mesenteric group of preaortic nodes**.

**PANCREATOSPLENIC NODES.** The pancreaticosplenic nodes accompany the splenic artery and are located adjacent to the posterior surface and upper border of the pancreas (Figs. 10-25; 10-26). One or two nodes of this group are found in the gastrosplenic ligament. The nodes at the hilum of the spleen, in addition to receiving channels from the splenic hilum, receive lymphatic vessels from the **left gastroepiploic nodes**. These latter nodes course between the layers of the greater omentum, along the greater curvature of the stomach. Thus, the pancreaticosplenic nodes receive afferent vessels from the stomach, spleen, and pancreas, and their efferent vessels join the **celiac group of preaortic nodes**.

### SUPERIOR MESENTERIC NODES

The superior mesenteric nodes, located around the root of the superior mesenteric artery, are numerous and large. They drain the visceral field supplied by branches of the superior mesenteric artery, and this includes part of the head of the pancreas, a portion of the duodenum, the entire jejunum, ileum, appendix, cecum, ascending colon, and most of the transverse colon. These nodes can be divided into the following groups:

- Mesenteric
- Ileocolic
- Right colic
- Middle colic

**MESENTERIC NODES.** The mesenteric nodes lie between the layers of the mesentery. They vary in number from 100 to 200, and may be grouped into three sets: one lying close to the wall of the small intestine, among the terminal twigs of the superior mesenteric artery; a second in relation to the loops and primary branches of the vessels; and a third along the proximal portion of the inferior mesenteric arterial trunk. They drain the jejunum and ileum along the intestinal branches of the superior mesenteric artery. Also, a part of the head of the pancreas and a portion of the duodenum are drained by nodes that course along the inferior pancreaticoduodenal branch of the superior mesenteric artery. Efferent vessels from the more proximal mesenteric nodes drain into the superior mesenteric group of preaortic nodes.

**ILEOCOLIC NODES.** Ten to twenty ileocolic lymph nodes form a chain around the ileocolic artery (Figs. 10-27; 10-28), but show a tendency to divide into two groups, one near the duodenum and another on the lower part of the trunk of the artery. Where the ileocolic artery divides into its terminal branches, the chain is broken up into several groups: **ileal**, in relation to the ileal branch of the artery; **anterior ileocolic**, usually three nodes in the ileocecal fold near the wall of the cecum; **posterior ileocolic**, mostly placed in the angle between the ileum and the colon, but partly lying dorsal to the cecum at its junction with the ascending colon; and a single **appendicular** node, between the layers of the mesenteriole of the vermiform appendix. These nodes receive lymph from the terminal portion of the ileum, the appendix and cecum, and from several inches of the proximal portion of the ascending colon. Their efferent channels drain into the **inferior mesenteric group of pancreatic nodes**.

**RIGHT COLIC NODES.** The right colic group of superior mesenteric nodes follows the course of the right colic artery and its branches as far as the medial border of the ascending colon. These nodes receive afferent vessels from **paracolic nodes** that are spaced along the medial border of the ascending colon. Their efferent vessels pass to the **superior mesenteric group of preaortic nodes**.

**MIDDLE COLIC NODES.** The middle colic nodes are numerous and accompany the middle colic artery and its branches to the

transverse colon, between the layers of the transverse mesocolon (Fig. 10-29). They are best developed in the area of the right and left colic flexures. The middle colic nodes receive afferent vessels from the paracolic nodes that lie along the mesenteric border of the transverse colon. Their efferent vessels course to the **superior mesenteric group of preaortic nodes**.

#### INFERIOR MESENTERIC NODES

The inferior mesenteric nodes are clustered around the stem of the inferior mesenteric artery and its branches. They drain the descending colon, sigmoid colon, and the upper part of the rectum, a field consistent with the blood supply of the inferior mesenteric artery. They are divided into the following groups:

Left colic  
Sigmoid  
Superior rectal

**LEFT COLIC NODES.** The left colic nodes lie along the course of the left colic branch of the inferior mesenteric artery, as far as the wall of the descending colon (Fig. 10-29). Along the medial border of the descending colon are found the paracolic nodes, which directly drain the large intestine. Efferent vessels from these nodes lead to the left colic nodes, which, in turn, send their efferent branches to the **inferior mesenteric group of preaortic nodes**.

**SIGMOID NODES.** The sigmoid lymph nodes are located between the layers of the sigmoid mesocolon, along the sigmoid branches of the inferior mesenteric artery (Fig. 10-29). They drain the sigmoid colon through the paracolic nodes that are located along the mesenteric border of the viscus. Efferent vessels from the sigmoid nodes terminate in the **inferior mesenteric group of preaortic nodes**.

**SUPERIOR RECTAL NODES.** The superior rectal group of lymph nodes courses along the superior rectal branch of the inferior mesenteric artery (Fig. 10-29). Lymphatic vessels from the rectum course to **pararectal nodes**, which are oriented longitudinally along the rectum and in contact with its muscular coat. From these nodes, efferent vessels pass to the superior rectal nodes, which then drain to the **inferior mesenteric group of preaortic nodes**.

## Lymphatic Vessels and Nodes of the Lower Limb

Most of the lymphatic vessels of the lower limb ascend either superficial or deep to groups of inguinal lymph nodes that lie in the upper anterior thigh, just below the inguinal ligament. Intermediate nodes are also found in the anterior leg and popliteal fossa, along the course of major blood vessels. In this section are described initially the lymphatic vessels of the lower limb and then the groups of lymph nodes.

### LYMPHATIC VESSELS OF THE LOWER LIMB

The lymphatic vessels of the lower limb consist of two sets, superficial and deep, and their distribution corresponds closely to that of the veins.

**SUPERFICIAL LYMPHATIC VESSELS.** The superficial lymphatic vessels of the lower limb lie in the superficial fascia, and are most numerous on the sole of the foot. They are divisible into two groups: a medial, which follows the course of the great saphenous vein, and a lateral, which accompanies the small saphenous vein.

**Fig. 10-37.** Lymph nodes of the popliteal fossa.

**Fig. 10-38.** Lateral view of the right popliteal region. A contrast medium was injected into a superficial lymphatic vessel behind the lateral malleolus. This outlined one of the lymphatic vessels ascending to a popliteal lymph node (marked by a cross) in the upper superficial region of the popliteal fossa. (From Battezzati and Ippolito, *The Lymphatic System*, John Wiley and Sons, New York, 1972.)

The **medial group** of superficial vessels is larger and more numerous than the lateral group, and commences on the tibial side and dorsum of the foot (Fig. 10-39). The vessels ascend both anterior and posterior to the me-

dial malleolus, course up the leg with the great saphenous vein, and pass with it behind the medial condyle of the femur to the groin. These vessels end in the **lower set of superficial inguinal lymph nodes** (Figs. 10-39; 10-40).

The **lateral group** of superficial vessels commences on the fibular side of the foot. Some of these vessels ascend on the anterior aspect of the leg, cross the tibia just below the knee, join the lymphatics on the medial side of the thigh, and end in the lower set of superficial inguinal nodes. Others pass behind the lateral malleolus, and accompanying the small saphenous vein, enter the **popliteal nodes** (Figs. 10-37; 10-38).

The superficial lymphatic vessels of the dorsal thigh curve around both the lateral and medial aspects of the limb to open into the *upper and lower* sets of the **superficial inguinal nodes**. From the lateral gluteal region, superficial lymphatic vessels course around the lateral hip region to reach the upper superficial inguinal nodes, while vessels from the anus and external genitalia (except the glans penis or clitoris) pass medially to the lower set of superficial inguinal nodes.

**DEEP LYMPHATIC VESSELS.** The deep lymphatic vessels are few in number and accompany the deep blood vessels. In the leg, they consist of three sets, the anterior tibial, posterior tibial, and peroneal, that accompany the corresponding blood vessels. Each of the sets consists of two or three lymphatic channels, and these enter the **popliteal lymph nodes**.

The deep lymphatic vessels of the gluteal and ischial regions follow the course of the corresponding blood vessels. Those accompanying the superior gluteal vessels end in a node that lies on the intrapelvic portion of the superior gluteal artery, near the upper border of the greater sciatic foramen. Those following the inferior gluteal vessels traverse one or two small nodes that lie below the piriformis muscle and end in the **internal iliac nodes**.

#### LYMPH NODES OF THE LOWER LIMB

The lymph nodes of the lower limb consist of the following:

- Anterior tibial node
- Popliteal nodes
- Superficial inguinal nodes
  - Upper group
  - Lower group
- Deep inguinal nodes

**ANTERIOR TIBIAL NODE.** The anterior tibial node is small and inconstantly found. When present, it lies on the interosseous mem-

**FIG. 10-39.** The superficial inguinal lymph nodes and lymphatic vessels of the lower limb.

**Fig. 10-40.** Normal lymphogram of the right inguinal region. 1, Superficial upper inguinal nodes; 2, deep inguinal nodes; 3, superficial lower inguinal nodes. (From de Roo, T., *Atlas of Lymphography*, J. B. Lippincott, Philadelphia, 1975.)

brane, between the tibia and fibula, adjacent to the anterior tibial vessels. It constitutes a substation in the course of the anterior tibial lymphatic trunks.

**POPLITEAL NODES.** Six or seven small popliteal nodes are embedded in the fat of the popliteal fossa (Figs. 10-37; 10-38). One lies immediately beneath the popliteal fascia, near the terminal part of the small saphenous vein, and drains the region from which this vein derives its tributaries. Another is placed between the popliteal artery and the posterior surface of the knee joint; it receives the lymphatic vessels from the knee joint, together with those that accompany the genicular arteries. The others lie at the sides of the popliteal vessels, and receive as afferents the trunks that accompany the anterior and posterior tibial blood vessels. Most of the efferent channels of the popliteal nodes course upward along the femoral ves-

sels to the **deep inguinal nodes**, but a few may accompany the great saphenous vein and end in the **superficial inguinal nodes**.

### INGUINAL NODES

The inguinal lymph nodes are located below the inguinal ligament in the upper anterior and medial thigh (Figs. 10-39; 10-40). These are the principal terminal nodes of the lower limb and they receive most of the efferent lymphatic channels from the foot, leg, and thigh. There are 12 to 20 inguinal nodes and they are divided into **superficial and deep inguinal sets**. Of these, the superficial inguinal nodes are more numerous and consist of upper and lower groups.

**SUPERFICIAL INGUINAL NODES.** The superficial inguinal lymph nodes lie in the fat between the skin and deep fascia, distal to the inguinal ligament. These nodes are divided into an **upper group**, forming a chain parallel to the inguinal ligament and extending from the anterior superior iliac spine to the femoral vessels, and a **lower group**, found in the superficial fascia surrounding the terminal part of the great saphenous vein (Figs. 10-39; 10-40).

The **upper group** of superficial inguinal nodes, consisting of five or six nodes, receives afferent lymphatic channels from the superficial structures of the gluteal region and from the superficial fascia of the anterior abdominal wall, below the umbilicus. Additionally, they receive superficial afferent channels from both the external genitalia and from the perianal region of the perineum.

The **lower group** of four or five superficial inguinal nodes (formerly called superficial subinguinal nodes) receives most of the superficial afferent lymphatic channels of the lower limb, as well as a few superficial vessels from both the urogenital and anal regions of the perineum.

Some efferent vessels from the superficial inguinal nodes drain to the **deep inguinal nodes** through the cribriform fascia, but most efferent channels pass into the pelvis by way of the femoral canal to the **external iliac nodes**.

**DEEP INGUINAL NODES.** The deep inguinal lymph nodes vary from one to three in number, and are located deep to the fascia lata, on the medial side of the femoral vein (Fig.

10-40). When three are present, the lowest node is situated just below the junction of the great saphenous and femoral veins, the intermediate node lies within the femoral canal, and the highest node (also known as the node of **Cloquet**<sup>1</sup> or **Rosenmüller**<sup>2</sup>) is located in the lateral part of the femoral ring. Of these, the intermediate node is the most inconstant of the three, but the highest is also frequently absent. The deep inguinal nodes receive afferent channels from the deep lymphatic vessels that accompany the femoral artery and vein, other lymphatic vessels from the glans penis or glans clitoris, and some efferent channels from the lower group of superficial lymph nodes. Efferent channels from the deep inguinal nodes pass through the femoral canal to the **external iliac nodes**.

## The Spleen

The spleen, a freely movable organ that is largely invested by peritoneum, is situated principally in the left hypochondriac region of the abdomen. Its posterior extremity extends into the epigastric region, and it is usually located between the fundus of the stomach and the diaphragm. It is soft and friable, highly vascular, and dark purplish. Although during fetal life and shortly after birth the spleen gives rise to new red blood corpuscles, this is not thought to occur normally in the adult human organ. Hemopoiesis does occur, however, in the spleens of many other adult vertebrates. The spleen, like certain other lymphoid organs, transforms lymphocytes into cells that produce antibodies or participate in cell-mediated immunologic reactions. Additionally, the spleen contains many macrophages that destroy old red blood cells, the hemoglobin of which is transformed into bilirubin and reused by the body.

The size and weight of the spleen are liable to extreme variations at different periods of life, in different individuals, and in the same individual under different conditions. In the adult, it is usually about 12 cm

in length, 7 cm in breadth, and 3 or 4 cm in thickness. The spleen increases in weight from 17 gm or less during the first year after birth to 170 gm at 20 years, and then slowly decreases to 122 gm at 76 to 80 years of age. Male spleens weigh more than female, and the variation in weight of adult spleens is from 100 to 250 gm, and in extreme instances, 50 to 400 gm. The size of the spleen increases during and after digestion, and varies according to the state of nutrition of the body, being large in well fed, and small in starved animals. In a patient with malarial fever it becomes much enlarged, weighing occasionally as much as 9 kg.<sup>1</sup>

## DEVELOPMENT OF THE SPLEEN

The spleen appears initially as several clusters of mesenchymal cells between the layers of the dorsal mesogastrium, near the tail of the pancreas during the fifth week (6-mm stage). These cellular aggregates become vascularized and soon fuse to form a lobulated structure. Evidence of this lobulation is still indicated in the adult spleen by notches usually present along the superior margin. With the rotation of the stomach, which results in the greater curvature being directed toward the left, the spleen is also carried to the left, and lies behind the stomach and in contact with the left kidney. The part of the dorsal mesogastrium that intervened between the spleen and the kidney becomes the **lienorenal ligament**, while that part between the spleen and the greater curvature of the stomach forms the **gastrosplenic ligament**.

**ANOMALIES IN DEVELOPMENT.** Simple **agenesis** of the spleen, splenic agenesis associated with cardiac defects, the occurrence of several spleens, each of good size (poly-splenia), the existence of a normal spleen with **accessory small spleens**, and the ectopic location of splenic tissue in the scrotum (**splenogonadal fusion**) that descended with the testis are abnormalities in development that have been described (Gray and Skandalakis, 1972).

FIG. 10-41. The visceral surface of the spleen.

#### RELATIONSHIPS OF THE ADULT SPLEEN

The spleen has two surfaces, diaphragmatic and visceral; two margins, superior and inferior; and two extremities, anterior and posterior (Figs. 10-41; 10-42).

**DIAPHRAGMATIC SURFACE.** The diaphragmatic surface of the spleen is smooth, convex, and directed upward, backward, and to the left, except toward its posterior extremity, where it is directed slightly medially. This surface is adjacent to the abdominal aspect of the diaphragm, which separates the spleen from the ninth, tenth, and eleventh ribs of the left side, and the intervening caudal border of the left lung and pleura (Fig. 10-42,C).

**VISCERAL SURFACE.** The visceral surface of the spleen is oriented toward the abdominal cavity, and it has gastric, renal, and colic areas (Fig. 10-41).

**Gastric Area.** The gastric area of the visceral surface of the spleen is directed anteriorly, upward, and medially (Fig. 10-41). It is broad and concave, and is in contact with the dorsal wall of the stomach, and below this, with the tail of the pancreas. It has near

its medial border a long fissure, or more frequently a series of depressions, termed the **hilus**. This is pierced by several irregular apertures for the entrance and exit of vessels and nerves.

**Renal Area.** The renal area of the visceral surface of the spleen is somewhat flattened and separated from the gastric area by an elevated ridge along the hilus. It is directed medially and downward and it is considerably narrower than the gastric area (Fig. 10-41). It is in anatomic relationship to the upper part of the anterior surface of the left kidney and occasionally with the upper aspect of the left suprarenal gland.

**Colic Area.** The colic area of the visceral surface of the spleen is flat and triangular. It rests on the left flexure of the large colon and the phrenicocolic ligament, and it is frequently in contact with the tail of the pancreas (Fig. 10-41).

**BORDERS OF THE SPLEEN.** The **superior border** is free, sharp, thin, and often notched, and it separates the diaphragmatic surface from the gastric area of the visceral surface. The **inferior border** is more rounded and more blunt than the superior border

(Fig. 10-41). It separates the renal area of the visceral surface from the diaphragmatic surface, and it corresponds to the lower border of the eleventh rib, lying between the diaphragm and left kidney.

**EXTREMITIES OF THE SPLEEN.** The **posterior extremity** is rounded and directed toward the vertebral column. The **anterior extremity** is broader and more expanded than the posterior (Fig. 10-41), extending between the superior and inferior borders and separating the colic area of the visceral surface from the diaphragmatic surface.

**PERITONEAL ATTACHMENTS.** The capsule of the spleen is completely covered, except at the hilus, by a closely adherent layer of visceral peritoneum. Developing between the layers of the dorsal mesogastrium, the spleen divides this mesentery into two portions. One extends between the stomach and the spleen and is called the **gastrosplenic ligament**. The other is interposed between the spleen and the dorsal body wall and is called the **phrenicolienal ligament** (Fig. 10-42,A).

The lower part of the phrenicolienal ligament, called the **lienorenal ligament**, extends to the left kidney, and between its layers are found the tail of the pancreas and the splenic vessels and nerves that course through the hilus of the spleen (Fig. 10-42,B). Between the leaves of the gastrosplenic ligament are found the short gastric and left gastroepiploic vessels.

Because these ligaments form the left boundary of the omental bursa (lesser sac), their outer surfaces are covered by peritoneum that surrounds the greater sac and their inner surfaces are covered by peritoneum that lines the omental bursa. The spleen itself is covered by greater sac peritoneum only, unless the gastrolial and phrenicolienal ligaments fail to meet at the hilum, in which condition a small area within the hilum may be covered by peritoneum that lines the omental bursa.

As pointed out previously, near the spleen are frequently found small nodules of splenic tissue. This is especially so in the gastrosplenic ligament and greater omentum, and these nodules may be either isolated or connected to the spleen by thin bands of splenic tissue. These are called accessory spleens, and their size varies from that of a pea to that of a plum.

## MICROSCOPIC STRUCTURE OF THE SPLEEN

The spleen is an encapsulated lymphatic organ, but it is unlike the lymph nodes because through the sinuses of the spleen venous blood filters, whereas through the sinuses of the lymph nodes the lymphatic fluid filters.

### CAPSULE AND TRABECULAE

The spleen is invested by two coats: an external serous layer and an internal fibroelastic capsule. From the latter, connective tissue trabeculae penetrate the substance of the spleen, separating it into many small compartments (Fig. 10-43).

**EXTERNAL SEROUS COAT.** The external serous coat is not an intrinsic part of the spleen because it is derived from the peritoneum. It is a thin, smooth layer of mesothelial cells, and it is intimately adherent to the underlying fibroelastic capsule. It invests the entire organ, except at the hilum and along the lines of reflection of the phrenicolienal and gastrosplenic ligaments.

**SPLENIC CAPSULE.** The spleen is enclosed in a rather heavy fibroelastic capsule that is composed of dense fibrous connective tissue, is rich in elastic fibers, and contains scattered fibroblasts and some smooth muscle cells. The capsule closely invests the organ, and at the hilum is prolonged inward upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibroelastic capsule, numerous small fibrous bands, called trabeculae, are given off in all directions. Because of the high content of elastic fibers in the capsule, the vascular sheaths, and the trabeculae, the spleen possesses a considerable ability to undergo variations in size.

**TRABECULAE.** The trabeculae are flattened strands of connective tissue that divide the spleen into many small intercommunicating compartments, each several millimeters in diameter (Fig. 10-43). Containing an even higher number of elastic fibers than the capsule, the trabeculae are scattered throughout the spleen, thereby forming a complex meshwork. The trabeculae arise from the branching of larger connective tissue sheaths that penetrate the organ at the hilum, while other trabecular strands branch from

**FIG. 10-42.** The splenic ligaments. A, The gastro-splenic ligament (part of the greater omentum) has been opened to reveal the splenic vessels and the short gastric vessels. B, Cross section through the spleen and fundus of the stomach; observe the gastro-splenic ligament oriented anteriorly and the lienorenal ligament oriented posteriorly. C, The spleen in relationship to the ninth, tenth, and eleventh ribs. Note the cut edges of the gastro-splenic and lienorenal ligaments. (From Thorek, P., *Anatomy in Surgery*, 2nd ed., J. B. Lippincott, Philadelphia, 1962.)

**Fig. 10-43.** Transverse section of the spleen, showing the trabecular tissue and the splenic vein and its tributaries. (From Henry Gray, 1854).

the internal capsular surface. Within the compartments outlined by the trabeculae is found the **splenic pulp**.

#### SPLENIC PULP

In a cross section of freshly cut spleen, small whitish to gray regions, measuring 0.25 to 1 mm in diameter, are seen scattered throughout a mass of soft, dark reddish-brown tissue. These lighter regions are collectively called the **white pulp** and individually are known as *lymphatic nodules* (or Malpighian<sup>1</sup> bodies), while the surrounding larger mass of darker tissue is called the **red pulp** (Fig. 10-44).

**WHITE PULP.** The white pulp of the spleen consists of many small masses of periarterial lymphocytes and other related cells. Arteries that enter the hilum of the spleen course along the trabecular meshwork and branch into smaller vessels. Supporting these smaller vessels are sheaths of reticular fibers, in the meshes of which are infiltrations of lymphocytes. As the arteries branch, they leave the trabeculae and eventually penetrate the red pulp. As the periarterial lymphatic sheaths surrounding the vessels leave the trabeculae, they become enlarged at certain sites to form the lymphatic nodules of

the white pulp (Fig. 10-44). The microscopic structure of these nodules, which have compact masses of lymphocytes enmeshed within a network of reticular fibers, is not significantly different from that of the germinal centers of lymph nodes.

**RED PULP.** The red pulp forms the main substance of the spleen (Fig. 10-44). It is composed of rich plexuses of tortuous venous sinuses. Between the sinuses are splenic cords that contain diffuse lymphatic cells, which include many macrophages, all the white blood cell types, many erythrocytes, and plasma cells, all enmeshed in a fine network formed by the processes of stellate reticular cells. Attached by perpendicular processes to the outer endothelial walls of the venous sinuses, the reticular cell bodies lie suspended within the splenic cords, and come into direct contact with the free cellular elements. The macrophages are often large and contain ingested and partly digested red blood cells and pigment.

Between the lymphoid tissue of the white pulp and the sinuses and splenic cords of the red pulp is a **marginal zone** that shows characteristics transitional between the two types of splenic tissue.

#### BLOOD VESSELS OF THE SPLEEN

**ARTERIES.** Derived as one of the branches of the celiac trunk, the **splenic artery** is remarkable for its size, being quite large in

<sup>1</sup>Marcello Malpighi (1628–1694): A great Italian microscope anatomist and embryologist (Bologna, Pisa, and Messina).

**FIG. 10-44.** A section through a portion of the human spleen, stained with hematoxylin and eosin.  $50\times$ . (From di Fiore, M., *Atlas of Human Histology*, 5th ed., Lea & Febiger, Philadelphia, 1981.)

proportion to the size of the organ, and also for its tortuous course. It divides into six or more branches, which enter the hilum and ramify throughout its substance. Each of these branches supplies chiefly that region of the spleen in which it ramifies, having no anastomosis with the majority of other branches. They course in the transverse axis of the organ and diminish in size during transit.

These initial branches of the splenic artery further subdivide into smaller muscular **trabecular arteries**, which course along the trabecular system (Fig. 10-45). Their adventitial coat blends with the connective tissue of the trabeculae, and they frequently are described as having trabecular sheaths, which similarly invest the veins emerging at the hilum and the incoming nerves. The trabecular arteries ultimately leave the trabecular sheaths and their tunica adventitia is replaced by packs of lymphocytes, enmeshed in reticular fibers, which form the white pulp. These vessels are then called the **central** (or follicular) **arteries**, and they contain one or two layers of smooth muscle. Central arteries are not accompanied by veins, and despite their name they are usually dis-

placed to an eccentric position in the splenic lymphatic nodules (Figs. 10-44; 10-45).

As the central arteries branch, they become reduced in diameter, and their sheaths of lymphoid tissue become considerably thinner. When central arteries become reduced to about  $50\mu$  in diameter, each vessel divides into two to six straight branches called **penicillar arteries**. These latter vessels, still surrounded by a single or double layer of lymphocytes, enter the red pulp, course for less than 1 mm, and branch into two or three arterial capillaries. At this point, the arterial capillaries are lined by endothelial cells and have no muscle or adventitial coats, but they do acquire a characteristic thick sheath that consists of concentrically arranged macrophages and reticular fibers. The diameter of these **sheathed capillaries** is about 6 to  $8\mu$ . Although found in the human spleen, these capillaries are more prominent in other animals, such as the dog.

After a short course, sheathed capillaries branch into normal capillaries. Blood from these fine arterial capillaries reaches the venous sinuses, but exactly how this occurs is still conjectural. Some authors claim that the arterial capillaries are connected with

**Fig. 10-45.** This diagram illustrates the course of blood within the spleen from arteries at the hilus, through the splenic pulp, the sinusoids, and back through the veins. The labels should be read sequentially from 1 to 10. (From Ham, A. W., *Histology*, 7th ed., J. B. Lippincott, Philadelphia, 1974.)

the venous sinuses in a *closed* system, and that the endothelial lining between them is complete. Other authors maintain that the endothelial connections are incomplete and in this open type of circulation, the arterial blood is thought to enter the splenic lymphatic cords and then to diffuse through the endothelium and into the venous sinuses (Fig. 10-45). The flow through the splenic pulp is controlled by rhythmic contraction and relaxation of individual and groups of arterioles.

**VENOUS SINUSES.** The venous sinuses of the red pulp are tortuous channels measuring 12 to 40  $\mu$  in diameter. Their walls are formed by long, narrow endothelial cells that are oriented longitudinally along the sinusoid wall. Their nuclei bulge into the lumen; however, their cytoplasmic processes do not form true intercellular junctions. More recent evidence indicates that they do not behave as fixed macrophages, as was

once thought. The endothelial cells are supported by circularly arranged reticular fibers that are continuous with the collagen fibers of the trabeculae. The reticular fibers form rings around the sinusoids.

**VEINS.** The venous sinuses open into the slender, thin-walled **veins of the splenic pulp**. These join to form the **trabecular veins**, which in turn unite to form the six or more branches of the **splenic vein** emerging from the hilus (Fig. 10-45).

#### LYMPHATIC VESSELS AND NERVES

**LYMPHATIC VESSELS.** Although few, if any, lymphatic vessels have been found in the lymphoid tissue of the splenic pulp in the human spleen, they have been described in some other mammals. Lymphatic vessels do exist in the capsule of the human spleen and along the larger trabeculae. They emerge at

the hilus with the veins and open into splenic nodes found at the hilus and into pancreaticosplenic nodes along the superior border of the pancreas.

**NERVES.** Nerve fibers to the spleen are derived from the celiac plexus and course along the splenic artery to the hilus. These are primarily unmyelinated postganglionic sympathetic fibers that are vasomotor in function. Some fibers from the right vagus nerve, however, also have been found coursing to the spleen. The nerve fibers enter the spleen at the hilus and course along the arteries as far as their trabecular and central branches. They terminate not only along the smooth musculature of the vessel walls, but within the splenic pulp as well.

## The Thymus

The thymus in an infant is a prominent organ, occupying the anterior superior mediastinum, but the thymus in an adult of advanced years may be scarcely recognizable because of atrophic changes (Fig. 10-46). It is situated between the sternum and great vessels, resting on the pericardium and overlapping somewhat the upper anterior borders of both lungs. At one time, the thymus was thought simply to function as a producer of lymphocytes. Only since the 1960s has the enormous importance of the thymus in the maturation of a competent immunologic system come to light. Although much still needs to be learned, the thymus is now recognized

as perhaps the key organ that contributes to the ability of the body to produce antibodies and to reject foreign tissues and cells.

## DEVELOPMENT OF THE THYMUS

During the latter part of the fifth prenatal week, when the developing embryo is only about 10 mm long, the primordia of the thymus appear on the anterior aspect of the third pharyngeal pouch, one on each side. At this same time, the inferior parathyroid glands develop as small solid masses on the dorsal aspect of the third pouch. Between the sixth and eighth weeks the developing thymus is initially recognized as two hollow endodermal elongations that descend into the thorax and then fuse in front of the developing great vessels. At this time, the inferior parathyroid glands usually separate from the thymus and come to rest on the posterior surface of the thyroid gland. Sometimes, however, the inferior parathyroid glands do not separate and their continued development occurs within the substance of the thymus, where they come to lie in the anterior mediastinum.

The fusion medially of the two thymic diverticula involves only the mesenchymal connective tissue into which the thymic tissue has grown, and there is no fusion of the parenchyma of the two developing lobes. The pharyngeal opening of each diverticulum, the **thymopharyngeal duct**, is soon obliterated, but this stalk may persist for a period of time as a cellular cord. Some in-

Fig. 10-46. The thymus of a full-term fetus; exposed *in situ*.

investigators have claimed that the anterior aspect of the fourth pharyngeal pouch also develops into a small amount of thymic tissue, but this has not been definitely established as a routine occurrence.

As the lobules continue to increase in size, their peripheral zones form the **cortex** of the thymus, in which many small lymphocytes are concentrated, and their central zones form the **medulla**, in which the cellular reticulum predominates. The thymus attains a weight of 12 to 14 gm before birth, but it does not reach its greatest relative size until the age of two years. It continues to grow until puberty, at which time it reaches its greatest absolute size, weighing about 35 gm. After adolescence it begins its process of involution.

**HISTOGENESIS OF THE THYMUS.** The cellular differentiation of the thymus commences when endodermal epithelial cells form solid cords that grow caudally into the surrounding mesenchyme tissue. Soon the tubular masses of epithelial cells are penetrated by blood vessels, and the cells change their shape into stellate cells. They still remain attached to each other by cellular processes, but what results is a cytotreticular meshwork arrangement. Some of the epithelial cells, instead of contributing to the cytotreticular meshwork, become arranged in concentric, spherical clusters called **thymic corpuscles** (or Hassall's<sup>1</sup> bodies), the centers of which appear to show degenerative changes (Fig. 10-49).

At about the eighth prenatal week, lymphocytes appear in the developing epithelial cytotreticular meshwork, filling the interstitial spaces between the epithelial cells. At one time some investigators believed that these lymphocytes were derived from the epithelial cells themselves, while others thought that they came from the mesenchymal cells. The weight of evidence now indicates, however, that the thymus (like the developing spleen, liver, and bone marrow) receives stem cells from the yolk sac in the embryo, whereas after birth the stem cells come from the bone marrow. These reach the thymus by way of the blood stream and they begin to differentiate into small lymphocytes, which in the thymus are called **thymocytes**. During embryogenesis, the pro-

liferation of thymocytes occurs at a high rate and large numbers of these leave the thymus to reside at many sites elsewhere in the body.

## RELATIONSHIPS OF THE THYMUS

The thymus consists of two lateral lobes that are held in close contact by connective tissue, which also encloses the whole organ in a distinct capsule. It is situated partly in the thorax and partly in the neck, extending from the fourth costal cartilage to the lower border of the thyroid gland (Fig. 10-46). In the neck, it lies anterior and lateral to the trachea, and deep to the origins of the sternohyoid and sternothyroid muscles. In the thorax, it occupies the anterior portion of the superior mediastinum; superficial to it is the sternum, and deep to it are the great vessels and the upper part of the fibrous pericardium. The two lobes generally differ in size and shape, the right frequently overlapping the left. The thymus has a pinkish gray color, is soft and lobulated, and at birth measures approximately 5 cm in length, 4 cm in width, and 6 mm in thickness. Of greater importance, however, is its weight at different periods of maturation from birth through adulthood and senility (described previously), at which times the organ alters significantly in size.

## MICROSCOPIC STRUCTURE OF THE THYMUS

The two lobes of the thymus are composed of numerous lobules, varying from 0.5 to 2 mm in diameter, which are incompletely separated from each other by delicate connective tissue. The parenchymal cells of one lobule are joined to those of adjacent ones by thin cellular interconnections. The lobules can be seen on stained sections with the unaided eye. Using low power magnification, two zones of tissue can be seen within each lobule, an outer **cortex** and an inner **medulla** (Fig. 10-47).

The *cortical* part consists primarily of a network of stellate **reticular cells** and their processes, which differentiated from endodermal epithelial cells, and numerous closely packed aggregations of lymphocytes called **thymocytes**, which occupy the spaces within the cytotreticulum (Fig. 10-48). The

<sup>1</sup>Arthur H. Hassall (1817-1894): An English physician and botanist (London).

**Fig. 10-47.** Section of thymus from full-term fetus, lightly stained with hematoxylin. 5  $\times$ .

medullary portion of a thymic lobule contains reticular cells of varying shapes. Whereas some maintain the stellate characteristics of reticular cells found in the cortex, others become elongated, somewhat flattened, and circularly arranged in lamellae to form the **thymic corpuscles**, which measure 0.03 to 0.10 mm in diameter (Fig. 10-49). The central core of these corpuscles consists of granular cells that appear to be degenerating. The medulla contains many fewer lymphocytes than the cortex.

The stroma of the thymus consists of a thin investing capsule and interlobular connective tissue septa, in which are found the blood vessels and nerves supplying the organ.

**VESSELS AND NERVES.** The **thymic arteries** are derived from mediastinal branches of the internal thoracic artery, and from branches of the inferior thyroid arteries. The **thymic veins** drain into the left brachiocephalic, the internal thoracic, and the inferior thyroid veins. From the interlobular septa, smaller arteries enter the depths of the lobular parenchyma along the cortical-medullary border. From these vessels capillaries penetrate and ramify within the cortex, while other small vessels course into the medulla. The returning capillaries and venules merge in a comparable manner and return to the interlobular septa in a similar course.

The **lymphatic vessels** that drain the thymus terminate in parasternal, anterior mediastinal, and tracheobronchial lymph nodes.

The **nerves** that supply the thymus are very small and are derived from both sym-

pathetic and vagal branches. Also distributed to the capsule of the thymus, but not penetrating the substance of the gland, are small branches from the phrenic nerves and from the superior root of the ansa cervicalis.

**INVOLUTION OF THE THYMUS.** The thymus commences gradual involutionary changes in early childhood, and this process is accelerated after puberty. This is a normal change and it is called **age involution**, but it may be superseded by a rapid **accidental involution** due to excessive stress, starvation, ionizing radiation, or acute disease. The small lymphocytes of the cortex disappear and the reticular tissue becomes compressed. The disappearing thymic tissue is likely to be replaced by adipose tissue, but the connective tissue capsule persists, retaining its original shape. With age the weight of the thymus is usually reduced significantly, and in an older individual what appears to be a yellowish-colored thymus, when sectioned, will reveal only small islands of thymic tissue surrounded by fat.

**FUNCTIONS OF THE THYMUS.** Only recently has the importance of the thymus been appreciated. One of the most exciting fields of research in the latter half of the twentieth century has been the work that has elucidated the cellular and humoral mechanisms by which the body achieves and maintains its immunologic defense. At one time it was thought that the thymus quite simply produced lymphocytes. Although this is one of its most important functions, it was not then realized how essential these specific lymphocytes, and probably certain humoral se-

**Fig. 10-48.** Low power view of the thymus showing its lobular structure. Note the darker cortical regions of each lobule surrounding the lighter medullary regions. Hematoxylin and eosin, 40  $\times$ . (From di Fiore, M., *Atlas of Human Histology*, 5th ed., Lea & Febiger, Philadelphia, 1981.)

**Fig. 10-49.** A medium-power view of the medullary region of a thymic lobule showing a thymic corpuscle (Hassall's body). Hematoxylin and eosin, 250  $\times$ . (From di Fiore, M., *Atlas of Human Histology*, 5th ed. Lea & Febiger, Philadelphia, 1981.)

cretions liberated by thymic cells, were to the maturation of the immunologic system. Removal of the thymus at birth results in animals that are immunologically incompetent. They cannot reject transplanted grafts, and being defenseless to the normal antigenic challenges of the environment, they soon die. Further, these animals show a deficiency of lymphocytes in the spleen, lymph nodes, and blood.

The epithelial (reticular) cells of the thymus probably have an endocrine function. It is thought that these cells secrete a hormone(s) that induces a capacity in lymphocytes, both of the thymus itself and elsewhere, and in plasma cells to form antibodies in response to antigens.

## Developmental and Gross Anatomy of the Central Nervous System

The human nervous system, having evolved from that of lower animals, accounts more nearly for the behaviors characteristic of people than does any other organ system in the body. Its role in the control and management of most functions of other organs and tissues allows for appropriate reactions to alterations in the environment and, thus, for survival. In this latter respect it functions comparably to the nervous systems of other mammals, but in its highly evolved integrative, communicative, reflective, creative, and acutely perceptive functions, the human nervous system lends to Man those abilities that have truly elevated our species above

all others. In addition to these more abstract functions of the human brain, which are common to all healthy members of our species, our individualities and the distinctive characteristics that give to each of us an identity and separate us, one from another, are also based in the structure and functions of our own personal nervous system.

In this chapter emphasis is placed on the developing nervous system and the gross anatomy of the spinal cord and brain. The detailed internal structure of the nervous system and the broad discipline of neurobiology and the other neurosciences will not be extensively recounted, for there are many excellent specialized textbooks in which these fascinating fields are handled more appropriately.

### Development of the Nervous System

The architectural and functional development of the nervous system and the underlying principles involved collectively form one of the most exciting chapters in all of biology. The descriptive and experimental neuroembryologist has had the task of explaining how and why the nervous system develops its infinite complexity. Similarities among the early developmental stages of many of the higher vertebrates have allowed us to gain much information about early human neurogenesis.

#### *Formation of Presumptive Neural Derivatives*

Each of us develops from the single-celled, fertilized ovum. Through successive mitotic divisions, the ovum becomes a fluid-filled ball of cells known as the **blastula**, within which exists an **inner cell mass** that is destined to become the embryo proper. This mass of cells is surrounded by an outer, flattened, cellular shell known as the **trophoblast**, which rapidly proliferates and invades the maternal uterine tissue. The use of vital staining techniques has made possible the discovery of regions of the living blastula that become the three primary germ layers: the **ectoderm**, **mesoderm**, and **endoderm**. Along the mid-dorsal line of the embryo at this early stage, there appears a **primitive streak**, an area of ectoderm where a faster

**FIG. 11-1.** Schematic sections through the neural groove and neural tube in successively older embryos. (Redrawn after W. J. Hamilton and H. W. Mossman, *Human Embryology*, 4th ed., Williams and Wilkins, Baltimore, 1972.)

proliferation of cells occurs. Because the entire nervous system is ectodermal in origin, it is at this time (15 to 17 days after fertilization) that the presumptive neural regions of the human embryo commence differential transformation.

In front of the primitive streak appears the **primitive knot** (Hensen's<sup>1</sup> node), from which extends the developing **notochord**. The flattened layer of ectoderm on the dorsal aspect of the embryo now becomes stratified, and this unequal growth of the **neural plate** leads to an infolding of the ectoderm and thus the formation of the **neural groove** (Fig. 11-1,A

and B). Coursing along the longitudinal axis of the embryo, the neural groove then becomes surrounded by the **neural folds**. As the process of invagination continues, the neural folds fuse to form the **neural tube**, the rostral part of which is broader and eventually develops into the brain, while the narrow caudal part forms the spinal cord (Fig. 11-1,C and D). The central lumen of the neural tube is retained as the ventricular system rostrally and as the central canal of the spinal cord caudally.

**NEURAL INDUCTION.** At these early developmental stages, the organization of the portion of the embryo that is destined to become the nervous system, i.e. essentially the neural plate and folds, appears to be under the inductive influence of underlying mesodermal elements. In their classic experiments, Spemann and Mangold (1924) first emphasized the necessity for the maintenance of physical contact between the neural ectoderm and the subjacent mesodermal tissue for normal neural development. When a particular part of an embryo is capable of liberating a chemical substance that causes the surrounding tissue to develop in a certain manner, the process is called **induction**. The biochemical substance is called the **evocator**, and the property exhibited by the surrounding tissue in response to the evocator is called **competence**.

Because mesoderm at the dorsal lip of the blastopore (and probably tissue in other regions of the primitive streak) is capable of directly inducing the formation of central neural tissue in the embryo, it is called a **primary organizer**. Although the chemical nature of the evocator is still unknown, several types of substances have been shown to have inductive effects.

The great significance of these early periods to the normal development of the complete mature central nervous system should be stressed. The shifting of only a few cells in the wrong direction, or the failure in growth or closure of a small part of the neural tube in an embryo 2 to 3 mm long, can result in embryonic death or serious malformation. For example, if the neural groove fails to close, or if having closed, it fails to separate completely from the overlying ectoderm, the development of the associated vertebrae is also abnormal, and a condition known as **spina bifida** results.

<sup>1</sup>Victor Hensen (1835–1924): A German embryologist and physiologist (Kiel).

### Histogenesis of the Neural Tube

The neural tube eventually separates from the layer of ectoderm that is destined to become skin and continues to develop subcutaneously. Rapid division and growth in the cephalic end of the neural tube occurs and soon the accumulations of nuclear masses in the walls of the neural tube become recognizable as forebrain, midbrain, and hindbrain.

In recent decades the histogenesis of the cellular elements that comprise the central nervous system has become a subject of enhanced scientific interest. For many years the pseudostratified, columnar, neuroepithelial structure of the very early neural tube, even before its closure, was described as consisting of several cell types. His (1889, 1904) proposed that from these cell types three layers develop: ependymal, mantle, and marginal. In His' schema, the innermost **ependymal layer** contains germinal cells that divide to form neuroblasts. These migrate through a wider layer of *spongioblasts* (precursors to the neuroglia) to form the **mantle layer** or gray matter region. The outermost **marginal layer** does not contain many cell bodies, but instead consists of many nerve processes (fibers) that eventually form the white matter.

### FOUR-ZONE SCHEMA RECOMMENDED.

A more recent and welcome clarification of the terminology, and a variation on the classic schema of His regarding histogenesis of the neural tube, is based on modern electron microscopic and autoradiographic findings (Boulder Committee, 1970). This proposal states that four geographic zones form in the developing vertebrate central nervous system: ventricular, subventricular, intermediate, and marginal (Fig. 11-2).

Within the **ventricular zone**, which borders the central lumen, a single pseudostratified columnar cell type called the ventricular cell exists (Fig. 11-2,A). This cellular element is the source of all neurons and macroglia (astrocytes and oligodendroglia) in the central nervous system. The germinal cells and the spongioblasts, which His considered different cell types, are in fact mitotic and intermitotic forms of the ventricular cell. The Fugita (1963a, b; 1964) and others have shown that as cells in this innermost ventricular zone (Fugita's matrix layer) pass through intermitotic and mitotic phases, their nuclei "elevate" away from and then return to the innermost region of the neural tube. During their intermitotic period (DNA synthetic phase), the ventricular cells have an elongated columnar form, and the nuclei are located away from the lumen in

**Fig. 11-2.** Schematic drawing of five stages (A-E) in the development of the vertebrate central nervous system, as described in the text. Abbreviations: CP, cortical plate; I, intermediate zone; M, marginal zone; S, subventricular zone; V, ventricular zone. (From Boulder Committee, *Anat. Rec.*, 116:257-262, 1970.)

the outer limit of the ventricular zone. When these columnar cells are ready to divide, thereby replicating their DNA, the cells become spherical, the nuclei move inward toward the surface of the ventricular lumen, and at this deepest portion in the wall of the neural tube, the cells divide.

Shortly after the formation of the ventricular zone, an outermost **marginal zone**, composed principally of the cytoplasmic processes of the ventricular cells, is recognizable (Fig. 11-2.B). As the ventricular cells continue to divide, some newly formed cells migrate outward from the ventricular zone to create an **intermediate zone**, interposed between the marginal and ventricular zones (Fig. 11-2.C). Certain cells that form this intermediate zone are immature nerve cells that have ceased to divide. As they mature, these cells develop axons and dendrites that course either within the intermediate zone or enter the more outlying marginal zone.

In certain parts of the developing neuraxis, such as the anterior region of the spinal cord, the intermediate zone remains relatively uniform. In the developing cerebrum and cerebellum, however, cell bodies within this zone migrate to form other layers, such as the cortical plate illustrated in Figure 11-2.D and E.

This more recent description of the process also recognizes a **subventricular zone** that eventually forms between the ventricular and intermediate zones (Fig. 11-2.D and E). Migrating to the subventricular zone are round proliferating cells that do not divide and descend during their intermitotic and mitotic phases. These cells give rise to the adult subependymal neuronal elements, as well as to the adult astrocytes and oligodendroglia, but not to the ependymal cells. From this subventricular zone, the neuroglial elements are thought to migrate to all other zones of the embryonic neuraxis.

### Development of the Spinal Cord

As a result of the proliferation and migration of ventricular cells into the intermediate zone, the lateral walls of the neural tube increase in thickness. In contrast, the roof plate and floor plate become quite thin, and the central lumen is rather narrow and slitlike (Fig. 11-3.B). The ventral part of each lateral wall further enlarges, and the middle portion of the lumen becomes altered on

**Fig. 11-3.** Diagrams illustrating four successive stages in the development of the alar (in black) and basal (in red) laminae of the spinal cord region. (From W. J. Hamilton and H. W. Mossman, *Human Embryology*, 4th ed., Williams and Wilkins, Baltimore, 1972.)

each side by the formation of a longitudinal groove, the **sulcus limitans** (Fig. 11-3). The sulcus indicates the area on the wall of the neural tube at which the dorsal or alar lamina is separated from the ventral or basal lamina. These laminae represent an early functional differentiation: the **alar lamina** or **alar plate** will become the sensory portion of the gray substance, and the **basal lamina** or **basal plate** will become the motor portion (Figs. 11-3; 11-4).

The basal lamina thickens, and in a cross section the intermediate zone (mantle layer) appears as an expanded region between the marginal and ventricular zones. This thickening is the rudiment of the **ventral gray column** or **ventral horn**. Its immature nerve cells send their axons out through the marginal layer to form the ventral roots of the spinal nerves (Fig. 11-4). The alar lamina also thickens gradually, becoming the **dorsal gray column** or **dorsal horn**. Later, axons from many of these cells grow rostrally and assist in the formation of the **dorsal and lateral white columns** or **funiculi** (Fig. 11-4). A few fibers cross to the opposite side and form the ventral white commissure.

**Fig. 11-4.** Transverse sections through the spinal cords of human embryos. A, Age about four and a half weeks; B, age about three months. (W. His.)

At the end of about the fourth week, nerve fibers begin to appear in the marginal layer. The first to develop are the short intersegmental fibers, which come from differentiating nerve cells in the intermediate zone. Fibers from the cells in the spinal ganglia also grow into the marginal zone and by the sixth week have formed a well-defined **oval bundle** in the peripheral part of the alar lamina (Fig. 11-4). This bundle gradually increases in size and spreads toward the midline from each side; it forms the rudiments of the dorsal funiculi, which are separated by the **dorsal median sulcus**. Long intersegmental fibers appear about the third month, and corticospinal fibers appear about the fifth month. Initially, all the nerve fibers are devoid of myelin, and the various bundles of fibers become myelinated at different times. Thus, the dorsal and ventral roots acquire myelin about the fifth month, and the corticospinal fibers, after the ninth month. The expanding growth of the **ventral horn** and **ventral funiculus** of the two sides causes these parts to bulge laterally beyond the floor plate, leaving a deep groove, the **ventral median fissure**, between the two ventral funiculi.

**SEGMENTATION.** Segmentation is the repetition of structural patterns at successive levels and is one of the earliest vertebrate characteristics of the human embryo. The first somites that are formed are the most ce-

phalic ones; they appear behind the auditory placode during the third week of development. Thereafter, the number of somites increases rapidly, so that by the fifth week there are already 38 pairs. The most constant of these developing myotomes are the eight cervical, twelve thoracic, five lumbar, and five sacral somites. These become innervated by the developing spinal nerves and create the segmental organization of the body, providing the basis for segmental reflex activities.

Corresponding to the development of the somites, the thickening of the wall of the neural tube is not uniform. This enlargement is somewhat greater at the sites at which the spinal nerves attach to the cord than in between, producing a beaded appearance and establishing the **neuromeres** or **segments**. The relative thickness of the spinal segments varies according to the size of the nerves and the bulk of the peripheral field that the nerve supplies. There exists no valid evidence to indicate that segmentation is a characteristic inherent in the early neuraxis. In contrast, experimental evidence has shown that segmentation in the nervous system is determined to a large extent by segmentation of the mesodermal somites. On the basis of the segmentation of the axial mesoderm, it is generally accepted that spinal nerve and ganglion segmentation is acquired secondarily. In later development, the long projection

**FIG. 11-5.** Diagrams showing four successive stages in the differential growth of the spinal cord in relation to the vertebral column and meninges. Note the elevation in the position of the caudal end of the cord and the increasing length and obliquity of the first sacral nerve, used here for reference. A, Eighth prenatal week; B, twenty-fourth prenatal week; C, newborn infant; D, adult. (From K. L. Moore, *The Developing Human*, W. B. Saunders, Philadelphia, 1973.)

tracts grow into the marginal zone, thereby obliterating the segmental appearance of the spinal cord.

**GROWTH OF THE SPINAL CORD WITHIN THE VERTEBRAL CANAL.** In embryos during the somite stages and until the third prenatal month, the spinal cord forms a long, slender tube curved to the shape of the embryo and extending its entire length as far as the coccygeal region (Fig. 11-5). The segmentally arranged spinal nerve roots emerge and enter the spinal cord at levels directly in line with their sites of origin. By the sixth month the caudal end of the cord reaches only as far as the upper part of the sacrum, while at birth it is on a level with the third lumbar vertebra. These positional changes continue during postnatal maturation, so that in the adult, the end of the spinal cord lies at the level of the intervertebral disc between the first and second lumbar vertebrae (Fig. 11-5).

This uneven growth and the marked cephalic flexure of the brain keep the rostral end of the maturing nervous system within

the cranial cavity. The adult spinal cord gives the appearance of having been pulled upward in the spinal canal, and the spinal nerves below the cervical level become more and more longitudinally displaced within the vertebral canal. Because these nerves must still emerge at their somatic structures through their respective intervertebral foramina, the lower end of the vertebral canal becomes filled with the long coursing roots of the lower spinal segments. These roots are located intradurally, and this region of the cord is called the **cauda equina**. The finely tapered end of the cord itself, still attached to the most distal part of the vertebral canal in the coccyx, is called the **filum terminale** (Fig. 11-5).

### *Development of the Spinal Nerves*

The continued maturation of young nerve cells in the ventrolateral portion of the intermediate zone of the spinal cord results in the formation of the **ventral roots**, whereas the

FIG. 11-6. Neural crest formation. Transverse section through third somite of nine somite rat embryo.

immature neurons in the dorsal root ganglia grow into the cord to form the **dorsal roots**.

**VENTRAL ROOTS.** As groups of nerve cells that form the gray matter in the basal plate continue to differentiate during the fifth week, they sprout delicate processes that emerge from the ventral horn and form the rudiments of the ventral roots. Many of these fibers, motor in function, course toward masses of differentiating striated muscle cells and eventually make contact.

**DORSAL ROOTS.** The dorsal roots, which develop differently than the ventral roots, form differentiating nerve cells in the dorsal root ganglia. During the sixth and seventh prenatal weeks, these young neurons send processes both centrally into the posterior gray matter of the spinal cord and peripherally to structures that are developing within their respective myotomes. The tissue

that forms the spinal ganglia is a ridge of neuroectodermal cells called the **neural crest** or **ganglion ridge**.

**The Neural Crest.** The neural crest forms from bands of ectodermal cells that originate early during the development of the nervous system and are located on the sides of the neural folds (Figs. 11-6; 11-7). As the folds begin to fuse, the neural crest cells from both sides form an aggregation of cells along the midline, dorsal to the neural tube and extending from the caudal part of the cephalic region all along the developing neuraxis (Fig. 11-7). After a short period of time, the neural crest cells once again become displaced bilaterally, undergo metameric segmentation, and begin to differentiate. The proliferating neural crest cells are gathered into paired spherical groups that correspond to each segment and will become the primi-

FIG. 11-7. Development of the human neural crest. A, 2.5 mm; B, 5.0 mm; C, 7.5 mm; D, longitudinal diagram of the early spinal cord showing the neural crest as a plate of tissue overlying the neural tube. The neural crest then divides into right and left portions, each of which will further subdivide segmentally. (After L. B. Arey, *Developmental Anatomy*, revised 7th ed., W. B. Saunders, Philadelphia, 1974.)

tive spinal ganglia. Some of the neural crest cells from the ventral part of each primitive ganglion separate and migrate peripherally to form the sympathetic ganglia and other neural crest derivatives.

In addition to the spinal ganglia and the ganglia of the sympathetic system, the neural crest gives origin to the parasympathetic ganglia in the head, along with the sensory ganglia associated with the trigeminal, facial, glossopharyngeal, and vagus nerves. Also derived from the neural crest are the neurilemma sheath cells of the peripheral nerves. Other neural crest cells become dispersed with the general mesenchyme and are responsible for the melanocytes in the skin, the cells of the adrenal medulla, the chromaffin cell system, and probably certain cartilages in the head.

**Neurons of the Spinal Ganglia.** As just stated, proliferation of the neural crest results in the formation of cellular aggregations, lateral to the neural tube, that are destined to become the sensory ganglia (Fig. 11-8,A). The developing neurons within these segmentally arranged ganglia give rise to the sensory fibers of the spinal nerves. During differentiation these nerve cells are initially **bipolar** due to the development of a primary process at either end. As their maturation continues, a majority of the cells in

mammals become **unipolar** as the two primary processes fuse into a single stem, which emerges from the neuronal soma (Fig. 11-8,B). Beyond the point of fusion, the axon divides like a T into two primary branches, one of which is directed centrally, and the other, peripherally. The centrally oriented branch grows into the neural tube as a sensory root fiber. As they penetrate the dorso-lateral wall of the neural tube, the sensory fibers bifurcate into ascending and descending branches within the marginal zone of the spinal cord. The fibers then enter the developing intermediate zone (gray matter) and come into synaptic connection with other maturing nerve cells there. The peripherally directed branches of the spinal ganglion cells become the afferent fibers in the cerebrospinal nerves.

Within the ganglia, some of the neural crest cells form capsules that surround the ganglion cell bodies. These supporting elements, which are disc-like and flattened, are called **satellite cells**. In contrast to what occurs in other ganglia, note that neurons in the sensory ganglia of the vestibulocochlear nerve remain bipolar throughout life.

**NERVE FIBER SHEATHS.** The axis cylinders in the developing peripheral nerves soon become surrounded by protective sheaths that are also ectodermal in origin. In the path

**FIG. 11-8.** Development of a human spinal nerve. A, Transverse section of the spinal cord and the dorsal and ventral roots in a 7-mm embryo. B, Longitudinal section of a spinal ganglion in an embryo of ten weeks, showing the transformation of bipolar ganglion cells into unipolar cells. These two figures come from the studies of S. Ramon y Cajal. (From L. B. Arey, *Developmental Anatomy*, revised 7th ed., W. B. Saunders, Philadelphia, 1974.)

of the outgrowing axons can be seen numerous spindle-shaped ectodermal cells that have migrated from the neural tube and the neural crest along the course of the ventral and dorsal roots. These are the **Schwann**<sup>1</sup> **cells**; they form not only a prominent morphologic feature in a developing peripheral nerve, but they also have an important role in the differentiation of the nerve fibers. They form the nucleated sheath, or **neurilemma**, of the peripheral nerve, and because they form myelin, they are comparable to the oligodendroglia of the central nervous system. The layers of **myelin** that form around the developing nerve fibers have been shown by electron microscopy not to be an extracellular substance, as was once believed, but alternating layers of lipids and protein which are plasma membranes of the Schwann cells wrapped around the axis cylinders in a spiral manner.

Although there is no question that the Schwann cells associated with the dorsal roots have a neural crest origin, it has been experimentally inferred that certain sheath cells accompanying the ventral root fibers may originate in the neural tube.

### **Development of the Brain**

The cephalic portion of the neural tube enlarges and begins to change its shape even before it is completely closed. The unequal growth in size and thickness of the different parts, together with the formation of certain flexures, establishes at an early stage three recognizable regions within the primitive brain: the **rhombencephalon** (or hindbrain), the **mesencephalon** (or midbrain), and the **prosencephalon** (or forebrain). During the fourth prenatal week in embryos of 3 to 4 mm, the first of the flexures to appear is the **midbrain** (or cephalic) **flexure** in the region of the mesencephalon (Fig. 11-9,A). By means of this flexure the forebrain makes a U-shaped bend ventrally over the rostral end of the notochord and foregut, causing the midbrain for a period of time to protrude dorsally as the most prominent part of the brain. The second bend, the **cervical flexure**, appears at the junction of the hindbrain and spinal cord at nearly the same time as does

the midbrain flexure. The cervical flexure continues to develop until the hindbrain and spinal cord form a right angle with each other (Fig. 11-9,A). It then gradually diminishes as the body posture changes and the head becomes erect, and it disappears some time after the sixth week. The third bend is named the **pontine flexure** because it occurs in the region of the future pons (Fig. 11-9,B). In contrast to the midbrain and cervical flexures, the convexity of the pontine flexure is directed anteriorly.

The sulci limitans, which divide the lateral walls of the spinal cord into alar and basal laminae, clearly extend rostrally through the hindbrain and midbrain. They also divide these brain stem regions of the neuraxis into alar (or dorsal) and basal (or ventral) laminae.

The early developing brain, being tubular in nature, contains a cavity that is continuous throughout the entire neuraxis, from the forebrain above to the lowest regions of the spinal cord. As development progresses and changes occur in the external shape of different regions of the central nervous system, the shape of the inner cavity also undergoes regional changes. In the forebrain the cavity becomes the **lateral ventricles** of the cerebral hemispheres and the **third ventricle** of the diencephalon (Fig. 11-9,C). The lumen narrows throughout the midbrain, eventually becoming the **cerebral aqueduct**, and opens once again as the **fourth ventricle** in the hindbrain. At the rostral end of the hindbrain, a constriction of the cavity results from a transverse invagination called the **dorsal rhombencephalic sulcus**. This region of the neuraxis is sometimes known as the **rhombencephalic isthmus**, and its cavity is continuous caudally with the fourth ventricle, which, in turn, becomes the **central canal** of the spinal cord (Fig. 11-9,C).

### **THE RHOMBENCEPHALON**

When the midbrain flexure appears, the rhombencephalon, or hindbrain, is as long as the forebrain and midbrain combined (Figs. 11-11; 11-12). For descriptive purposes, the rhombencephalon is divided into a more caudal portion called the **myelencephalon**, which forms the **medulla oblongata**, and a more cranial part, the **metencephalon**, which forms the **cerebellum** and **pons**.

**THE MYELENCEPHALON.** The caudal part of

<sup>1</sup>Theodore Schwann (1810-1882): A German histologist and physiologist who was a professor at Liège in Belgium.

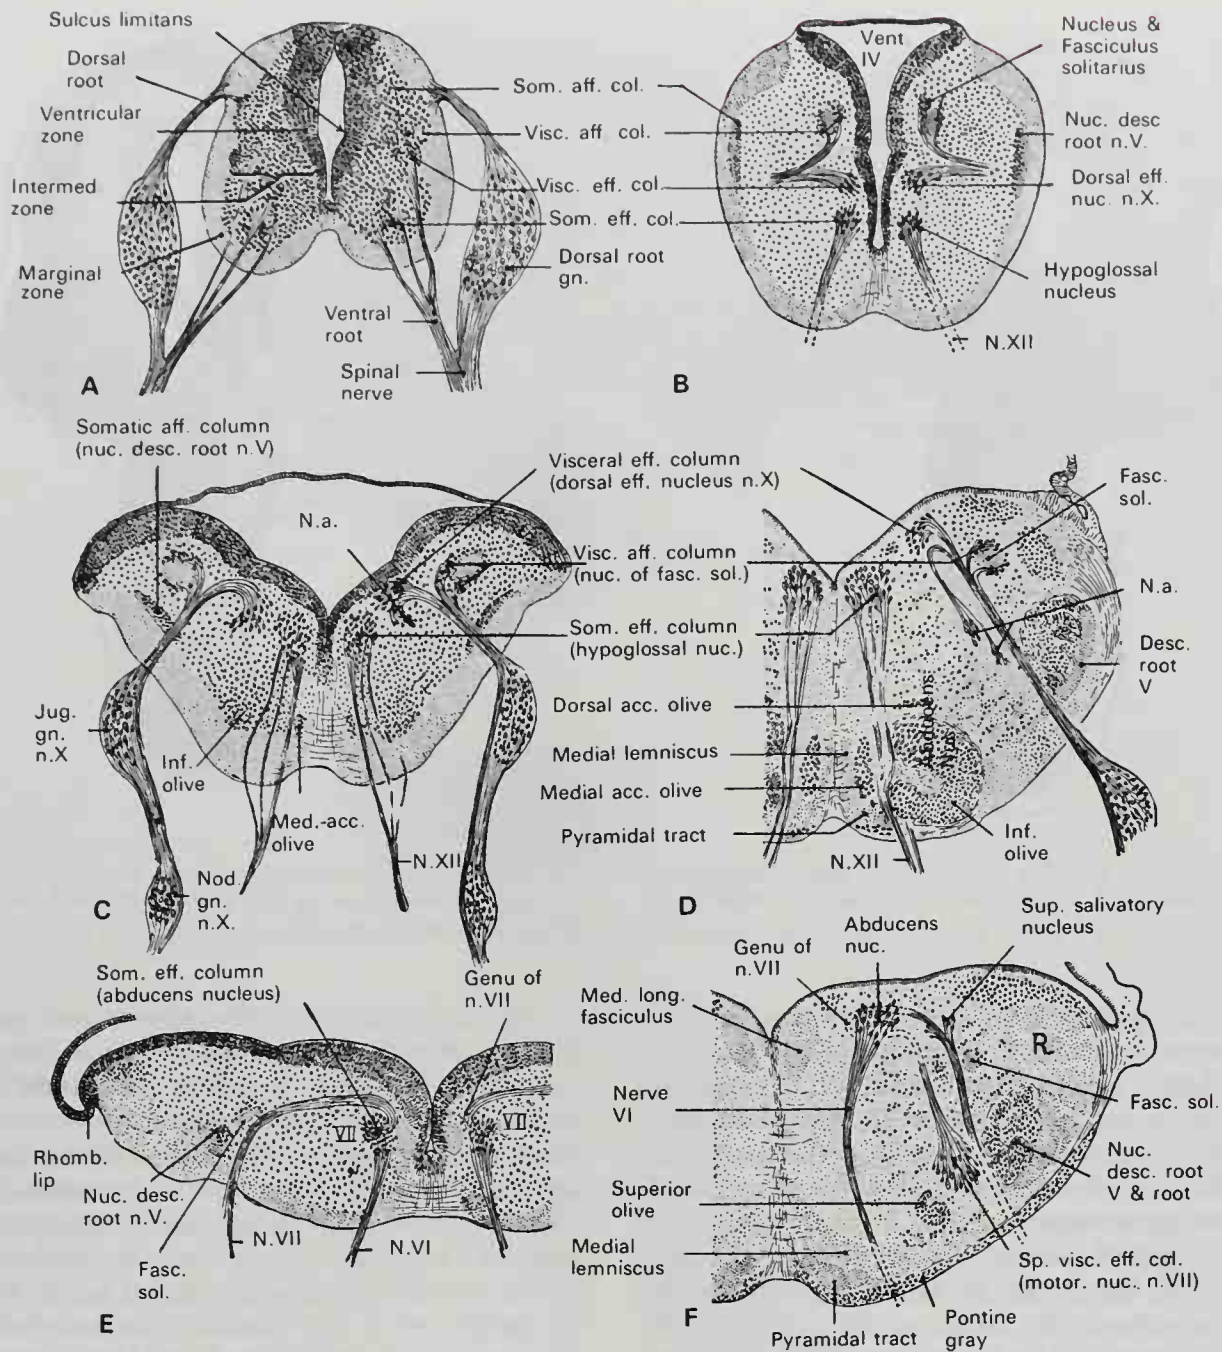

**FIG. 11-9.** A, Flexures of the human brain in 6-mm embryo (early part of fifth week). B, Flexures of the human brain in 14-mm embryo (early part of sixth week). C, Longitudinal hemisection of human brain in an 11-mm embryo (end of fifth week), showing the internal cavities. (Redrawn after L. B. Arey, *Developmental Anatomy*, revised 7th ed., W. B. Saunders, Philadelphia, 1974.)

the hindbrain is the myelencephalon, and it forms the medulla oblongata. At first the medulla is similar to the spinal cord, consisting of a roof plate, floor plate, and lateral plates of alar and basal laminae. The roof plate becomes greatly stretched and thinned at an early stage (Fig. 11-10,B and C), but the floor plate holds the lateral plates together so that they diverge and flatten simultaneously. The sulcus limitans persists, but now it separates a laterally placed alar lamina from a more medially placed basal lamina. The functional pattern remains similar to the spinal cord with a sensory alar plate, a motor basal plate, and autonomic nuclei along the sulcus limitans (Fig. 11-10,C, D, and E).

Sensory fibers from the neural crest ganglia of the glossopharyngeal and vagus nerves form a bundle opposite the sulcus limitans. Called the **tractus solitarius** (Fig. 11-10,B), it corresponds to the oval bundle of the primitive spinal cord (Fig. 11-4,A). At first it is in contact with the outer surface of

the alar lamina, but it later is buried by the overgrowth of neighboring parts (Fig. 11-10,D). At about five weeks, the part of the alar lamina next to the floor plate bends over laterally, forming the **rhombic lip** (Figs. 11-10,E; 11-13). The rhombic lip folds downward, over the main part of the alar lamina, fuses with it, and buries the tractus solitarius and spinal root of the trigeminal nerve. Later, the nodulus and flocculus of the cerebellum develop from the rhombic lip.

Although the basal plate corresponds in function to the ventral horn of the spinal cord because both give rise to motor fibers, in the basal plate the cells become arranged in groups or nuclei instead of continuous columns. In addition, neuroblasts migrate from the alar plate and rhombic lip into the basal lamina and become aggregated in the **olivary nuclei** (Fig. 11-10,D). Many of the fibers from these cells cross the midline of the floor plate and thus constitute the rudiment of the **raphe of the medulla**. The accumula-

tion of these cells and fibers in the ventral part of the basal plate pushes the motor nuclei deep into the interior, and in the adult they are found close to the interior lumen. The change is further accentuated by the

development of the pyramids at about the fourth month and by the fiber connections of the cerebellum. On the floor of the fourth ventricle, the rhomboid fossa—a series of six temporary transverse **rhombic grooves**—ap-

pears. The most cephalic, or first and second, grooves lie over the trigeminal nucleus; the third groove lies over the facial nucleus; the fourth, over the abducent nucleus; the fifth, over the glossopharyngeal nucleus; and the sixth, over the nucleus of the vagus nerve.

**THE METENCEPHALON.** The metencephalon is the rostral portion of the hindbrain, and it extends from the pontine flexure to the rhombencephalic isthmus. Its cavity is the rostral part of the fourth ventricle. Two regions of the neuraxis, the **pons** ventrally and the **cerebellum** dorsally, are derived from the metencephalon (Fig. 11-14).

**The Pons.** The pons consists of a dorsal, more primitive, and phylogenetically older part called the **pontine tegmentum**, which forms a thick floor for the fourth ventricle. Its structure in many ways resembles that of the medulla oblongata and it contains the upward continuation of many structures found in the medulla. In contrast, the **basilar** or **ventral portion of the pons** is a more recent and distinctly mammalian acquisition, since through it course fiber systems that interconnect the cerebral cortex and the cerebellar regions.

The roof plate of the embryonic pons forms a thin sheet of white matter in front of the cerebellar cortex called the **medullary velum**. The **basal plates**, located ventral to the sulci limitans, as in the myelencephalon and spinal cord, form motor neurons (Fig. 11-15). In the pons these contribute general somatic efferent fibers for the **abducens nerve**, which supplies the lateral rectus muscle in the orbit, and special visceral efferent neurons for the **trigeminal** and **facial nerves**, which supply the muscles derived from the first and second branchial arches. Additionally, preganglionic parasympathetic general visceral motor neurons are formed in the **superior salivatory nucleus**. Their axons also emerge with the facial nerve to synapse peripherally in the pterygopalatine and submandibular ganglia. The basal plate also contributes neuronal elements to the **reticular formation**.

The **alar plates**, located dorsal to the sulci limitans, form the relay nuclei for sensory components in the **trigeminal**, **facial**, and **vestibulocochlear nerves** (Fig. 11-15). The **sensory nucleus of the trigeminal nerve**, found in the pontine tegmentum and also

Fig. 11-13. Exterior of the brain of a human embryo of about five weeks. (From a model by W. His.)

extending caudally into the medulla oblongata, receives general sensory afferent trigeminal fibers. Special and general visceral afferent fibers course in the pons with the facial nerve to enter the **tractus** and **nucleus solitarius**, and the **vestibular** and **cochlear nuclei** receive special sensory afferent fibers from the vestibulocochlear nerve. The **floor plate** of the developing pons forms a midline raphe, as it does in the myelencephalon.

The ventrally located basilar portion of the pons contains the large **pontine nuclei**, which are formed by cells that migrate from the alar plates of both the myelencephalon and metencephalon. Fibers from the cerebral cortex enter these nuclei, whereas fibers from the pontine nuclei cross the midline and course to the cerebellum by way of the **middle cerebellar peduncles**.

**The Cerebellum.** Principally due to the pontine flexure, the dorsolateral parts of the alar plates in the cephalic portion of the hindbrain bend laterally and posteriorly to form the **rhombic lips** (Figs. 11-13; 11-16). The rostral part of each rhombic lip becomes thickened and, together with the alar plates in the rostral rhombencephalon,

forms the rudiments of the cerebellum (Fig. 11-14). Initially, the two rhombic lips partially project into the fourth ventricle and partially onto the dorsal surface of the metencephalon above the attachment of the roof plate. As the pontine flexure deepens, the rhombic lips become compressed, which causes them to fuse, thereby forming the **transverse cerebellar plate**. After the third month, this plate becomes differentiated into an unpaired midline portion, which becomes the **vermis**, and symmetrically shaped lateral portions, which develop into the **cerebellar hemispheres**. At this stage the developing cerebellum assumes a "dumb-bell" appearance, and further growth is principally the result of enlargement of its extraventricular part. Because of this so-called eversion, the cerebellum becomes essentially an extraventricular structure, overlying the fourth ventricle.

The outer surface of the cerebellum is initially smooth. Soon after the third month, however, the first of the cerebellar fissures appears, separating the **nodulus** and the **floculus** from the rest of the vermis and the lateral cerebellar lobes. This is called the **pos-**

FIG. 11-14. Interior of the brain of a human embryo of about five weeks. (From a model by W. His.)

terolateral fissure, behind which is the phylogenetically older **flocculonodular node**, importantly related to the vestibular system, and in front of which is the more rapidly growing cerebellar hemispheres. During the fourth and fifth months this rapid growth results in the formation of a number of fis-

tures that separate newly formed lobules in the cerebellar hemispheres. These include the **primary fissure**, which courses transversely and deeply to separate the paleocerebellar **anterior lobe** from the neocerebellar **posterior lobe**, as well as several other transverse fissures, including (from back to front) the **secondary fissure**, the **prepyramidal fissure**, the **horizontal fissure**, and the **posterior superior fissure**.

FIG. 11-15. Diagrammatic representation of the basal and alar plates of the metencephalon. Note the motor nuclei of the basal plates, the sensory nuclei of the alar plates, and the pontine nuclei located more ventrally. (From J. Langman, *Medical Embryology*, Williams and Wilkins, Baltimore, 1963.)

### THE MESENCEPHALON

The mesencephalon, or midbrain, develops around a primitive neural cavity that eventually is reduced in diameter to form the **cerebral aqueduct** (of Sylvius<sup>1</sup>). The narrow canal joins the lumen of the diencephalon (the third ventricle) rostrally with that of the rhombencephalon (the fourth ventricle) caudally. Three major regions of the embryonic neural tube become differentiated in

<sup>1</sup>Franciscus Sylvius (Latinized form of François Dubois, or de la Boë (1614–1672): A Dutch physician and anatomist (Leyden).

**FIG. 11-16.** Hindbrain of a human embryo of three months—viewed from behind and partly from the left side. (From a model by W. His.)

this part of the brain stem. These are the **tectum**, which develops dorsal to the cerebral aqueduct, and the midbrain **tegmentum** and **cerebral peduncles**, which form ventral and lateral to the aqueduct.

The midbrain tectum develops from the two alar laminae that invade the roof plate of the original neural tube. As in other regions of the neuraxis, cells from the alar plates develop into structures related to sensory functions, and in the midbrain tectum, they form the **corpora quadrigemina**. These four bodies are the paired inferior and superior colliculi, which serve as important relay centers for the integration of reflexes initiated by both auditory and visual impulses (Fig. 11-17).

The basal plate forms the tegmentum of the midbrain and from it originate the motor

nuclei of the **oculomotor** and **trochlear nerves** (Fig. 11-17). These general somatic efferent fibers supply the extraocular musculature that is formed within the preotic myotomes. Also formed by the basal plate are the general visceral efferent neurons of the **Edinger<sup>2</sup>-Westphal<sup>3</sup> nucleus**, preganglionic parasympathetic nerve cells that emerge with the oculomotor nerve to synapse in the ciliary ganglion. From this ganglion, postganglionic fibers supply the sphincter of the pupil.

The ventrolateral aspect of the basal plates receives large numbers of descending corticofugal fibers destined for the pons, medulla oblongata, and spinal cord. These form the **crura cerebri** or cerebral peduncles, which are separated from the tegmental region on both sides by nuclear masses called the **substantia nigra** (Fig. 11-17). The cells that form the **mesencephalic reticular formation**, as well as the **red nucleus**, are thought by some investigators to migrate from the alar plates into the tegmental regions. Others have claimed that these midbrain elements develop *in situ* from basal plate cells. There is also conjecture relating to the origin of the cells that form the **substantia nigra**.

### THE PROSENCEPHALON

At early stages, transverse sections of the prosencephalon, or **forebrain**, display the same parts as those that are seen at similar

**FIG. 11-17.** Diagrams showing the differentiation of midbrain structures from alar and basal plates. The arrows in A indicate the migration of alar plate cells, which form the red nucleus and substantia nigra. (From J. Langman, *Medical Embryology*, Williams and Wilkins, Baltimore, 1963.)

<sup>2</sup>Ludwig Edinger (1855-1918): A German anatomist and neurologist (Frankfurt-am-Main).

<sup>3</sup>Karl F. O. Westphal (1833-1890): A German neurologist and psychiatrist (Berlin).

stages of development in the spinal cord and medulla: namely, thick lateral walls connected by thin roof and floor plates. Although many investigators believe that the sulcus limitans does not extend forward beyond the midbrain and that the prosencephalon is formed primarily from the alar laminae, others believe that the hypothalamus is derived from the basal laminae and that the rest of the forebrain forms from the alar laminae. The latter point to the **hypothalamic sulcus**, which continues forward as far as the optic recess and might be considered analogous to the sulcus limitans. Irrespective of this matter, the telencephalon gives origin to all of the central nervous system cranial to the midbrain.

At a very early period, even before the closure of the cranial part of the neural tube, the **optic vesicles** appear as diverticula on each side of the forebrain. Initially they communicate with the forebrain vesicle by relatively wide openings. Later the proximal part of the vesicle is narrowed into the **optic stalk** (Figs. 11-11 to 11-14), and the peripheral part is expanded into the **optic cup**. The cavity of the vesicle eventually disappears, and the stalk is invaded by nerve fibers and becomes the **optic nerve** and tract. The optic cup becomes the **retina**.

After closure of the neural tube, the lateral walls of the forebrain grow anteriorly and ventrally much more rapidly than the median portion, resulting in the formation of a large pouch on each side, the **cerebral hemispheres** (Figs. 11-11; 11-13). The cavities within the pouches are the rudiments of the **lateral ventricles** and their intercommunications become the future **interventricular foramina of Monro**<sup>4</sup> (Figs. 11-12; 11-14). The median portion of the wall of the forebrain vesicle, formed by the anterior part of the roof plate, consists of a thin lamina that stretches from the interventricular foramina to the recess at the base of the optic stalk called the **lamina terminalis**. The rostral part of the forebrain, including the hemispheres, is the **telencephalon** or **endbrain**, and the caudal part is called the **diencephalon** or **intermediate brain**. The cavity of the median part of the forebrain vesicle becomes the **third ventricle**.

**THE DIENCEPHALON.** The diencephalon

gives rise to the **thalamus**, **metathalamus**, **epithalamus**, and **hypothalamus** (Figs. 11-12; 11-14; 11-18). A groove in the lateral wall of this part of the forebrain vesicle, the **hypothalamic sulcus**, separates the epithalamus, metathalamus, and thalamus, located more dorsally, from the hypothalamus, located ventrally. The *caudal* extent of the diencephalon consists of a plane drawn between the posterior commissure dorsally and the mammillary bodies ventrally, while *rostrally* it extends to the cerebral hemispheres and forms the telencephalon. At the base of the brain the diencephalon extends rostrally to a site a few millimeters anterior to the optic chiasma.

The **thalamus** arises as a thickening of the cephalic two-thirds of the alar plate. For some time it is visible as a prominence on the external surface of the brain (Figs. 11-11; 11-13), but it later becomes buried by the overgrowth of the hemispheres (Fig. 11-18). The thalami of the two sides protrude medially into the ventricular cavity and eventually join across the midline in a small commissure-like junction of gray substance called the **interthalamic adhesion**. This was formerly termed the **massa intermedia**.

The **metathalamus** consists of the **medial** and **lateral geniculate bodies**, which appear as slight prominences on the outer surface of the alar lamina. The medial geniculate bodies are relay stations for the transmission of auditory impulses, while the lateral geniculate bodies function as relay centers in the visual pathways.

The **epithalamus** includes the **pineal body**, the **posterior commissure**, and the **habenular trigone**. The pineal body arises as an evagination of the roof plate between the thalamus and the colliculi (Fig. 11-18). The habenular trigone, consisting of the habenular nuclei and the habenular commissure, develops in the roof plate just rostral to the pineal gland, and the **posterior commissure** develops just caudal to it. The roof plate of the diencephalon rostral to the pineal gland remains thin and epithelial in character and becomes invaginated by the **choroid plexus** of the third ventricle. The choroid plexus consists of modified ependymal cells that form a close functional relationship with blood vessels in the pia mater, and as elsewhere in the ventricular system, it secretes cerebrospinal fluid.

The **hypothalamus** is formed from the

<sup>4</sup>Alexander Monro Secundus (1733-1817): A Scottish anatomist and surgeon (Edinburgh).

FIG. 11-18. Median sagittal section of brain of human embryo of three months. (From a model by W. His.)

portion of the lateral walls of the diencephalon located below the hypothalamic sulcus (Figs. 11-12; 11-14; 11-18). One group of hypothalamic nuclei that develops becomes importantly related to many visceral and endocrine functions, as well as to the innate behaviors of feeding, drinking, and sleeping. Caudally the **mammillary bodies** are formed; initially these arise as a single ventrally protruding structure that later during the third prenatal month becomes divided by a midline furrow (Figs. 11-13; 11-14).

Anterior to the mammillary bodies the tuber cinereum is formed, and in front of this a diverticulum develops in the hypothalamic floor and gives rise to the **infundibulum** and **posterior lobe of the pituitary gland** (Fig. 11-18). In contrast, the anterior lobe of the pituitary gland develops from an ectodermal diverticulum called **Rathke's<sup>1</sup> pouch**. This latter outgrowth appears in the roof of the stomodeum during the middle of the third week. It extends upward toward the floor of the hypothalamus, and as it makes contact with the posterior lobe, it loses its

attachment on the pharyngeal roof during the sixth week.

The optic part of the hypothalamus initially is represented by two diverticula, the **optic vesicles**. Peripherally the optic cup forms the retina, whereas the optic stalk is retained as the pathway through which the ingrowing optic nerve fibers from the ganglionic layer of the retina form the **optic chiasma** and **optic tract**. The optic chiasma, located rostrally in the hypothalamic floor, forms the boundary between the diencephalon and telencephalon at the base of the brain.

**THE TELENCEPHALON.** The telencephalon is the most rostral portion of the developing neuraxis, and early during its formation it consists of two lateral diverticula and an interconnecting median part, the **lamina terminalis**, which is continuous with the diencephalon. The cavities of the diverticula represent the **lateral ventricles** and their walls become thickened to form the substance of the **cerebral hemispheres**. The cavity of the median portion is the most rostral extent of the third ventricle. Initially, the lateral ventricles widely communicate with the third ventricle, but eventually, as the cerebral hemispheres grow, these communications become the slit-like interventricular foramina.

The cerebral hemispheres expand rapidly after the sixth week, and by the fourth month almost completely cover the diencephalon, mesencephalon, and cerebellum (Fig. 11-18). The medial surfaces of the two hemispheres come into contact, which accounts for their flattened appearance and results in the formation of the **longitudinal cerebral fissure**, which intervenes between the hemispheres. This enormous growth of the cerebral hemispheres is characteristic of mammalian brains, especially the human brain. It is convenient and functionally relevant to describe the further development of the following principal parts of each cerebral hemisphere: the **rhinencephalon** and **archeopallium**, the **corpus striatum**, and the **neopallium**.

**Rhinencephalon and Archeopallium.** Continued use of the term **rhinencephalon** (olfactory brain) can be justified only when the structures incorporated within its definition are clearly stated. Confusion arises because authors have frequently used the term loosely to include many structures that are

<sup>1</sup>Martin H. Rathke (1793-1860): A German anatomist and zoologist (Königsburg).

not directly related to olfaction, but are associated instead with emotional and visceral functions (such as mating behavior, feeding, aggressivity, and fear)—functions that, especially in lower vertebrates, depend importantly on olfactory cues. In this book, the term **rhinencephalon** is used strictly to include the **olfactory bulb** and those forebrain regions that receive nerve fibers directly from it. Thus, in addition to the olfactory bulb, the rhinencephalon includes the **olfactory tracts**, the **medial**, **intermediate**, and **lateral olfactory striae**, the **olfactory trigone** (formed where the striae diverge), the **anterior olfactory nucleus**, the **olfactory tubercle** (anterior perforated substance), the **cortico-medial group of nuclei in the amygdaloid complex**, and the **prepiriform** and **periamygdaloid cortex** of the piriform lobe. In essence, this represents the olfactory bulb, its tracts, and the **paleopallium**, the so-called olfactory cortex. Because the **hippocampal formation** in mammals does not appear to receive major projections of olfactory fibers directly, its structures are included in the term **archeopallium**.

The rhinencephalon and archeopallium are phylogenetically the oldest portions of the telencephalon, and in fishes, amphibia, and reptiles they constitute virtually the entire cerebral hemisphere. The rhinencephalic primordia first appear on the medial aspect of the anteroventral surface of each developing cerebral hemisphere during the latter part of the fifth week (Figs. 11-13; 11-14). Externally, a slight longitudinal ridge or diverticulum appears which corresponds to a furrow that forms on the inner aspect of the hemisphere, close to the lamina terminalis. The rhinencephalon is separated from the lateral surface of the hemisphere by the **rhinal sulcus** and is continuous caudally with the portion of the hemisphere that will form the anteromedial end of the temporal lobe. As development continues, the longitudinal ridge becomes divided by a groove into an anterior and a posterior part. The rostral part of the ridge is the primitive **olfactory lobe**, while the caudal part is the **piriform lobe** (Fig. 11-19). From the rostral part of the longitudinal ridge, a hollow shaft grows forward, the cavity of which initially retains a communication with the lateral ventricle. During the third month, the stalk loses its cavity and becomes solid, forming the primitive olfactory bulb and tract. The proximal

**Fig. 11-19.** Inferior surface of brain of embryo at beginning of fourth month. (From Kollmann.)

part of the primitive olfactory lobe is connected with the parolfactory or subcallosal area, adjacent to the lamina terminalis on the medial surface of the hemisphere, by the **medial olfactory gyrus** (Fig. 11-19).

From the caudal part of the primitive olfactory ridge develop the anterior perforated substance and piriform lobe (Fig. 11-19). At the beginning of the fourth month, the piriform lobe forms a curved elevation that is continuous behind with the medial surface of the future temporal lobe. Interconnected rostrally to the olfactory lobe by the **lateral olfactory gyrus** (or prepiriform region), the surface of the piriform lobe is marked at this stage by the gyrus ambiens and the gyrus semilunaris (Fig. 11-19). These develop into the corticomedial part of the amygdala and the **lumen insulae**. The adult piriform lobe, bounded laterally by the rhinal sulcus, is divided into the prepiriform, periamygdaloid, and entorhinal regions. The prepiriform and periamygdaloid regions receive direct olfactory bulb fibers by way of the lateral olfactory tract, while the entorhinal region, which forms a large part of the parahippocampal gyrus, receives projections from the prepiriform cortex, but none directly from the olfactory bulb.

The adult **archeopallium** consists of the **hippocampus** (cornu ammonis), the **dentate gyrus**, and the **subicular part of the parahippocampal gyrus**. Together these structures are also frequently called the **hippocampal formation**, and before the appear-

ance of the corpus callosum, they develop on the medial wall of the cerebral hemisphere along a line parallel with, but above and in front of, the choroid fissure. Becoming folded into the cavity of the lateral ventricle, so that the prominence bulging into the ventricle forms the hippocampus, the invagination is accompanied by the development of a corresponding fissure, the **hippocampal sulcus**, on the medial surface of the cerebral hemisphere. Soon the marginal zone of the invagination differentiates to form the dentate gyrus, while inferiorly and laterally the hippocampus merges with the cortex of the parahippocampal gyrus by means of the subiculum. As the infolding proceeds, the hippocampal fissure is elongated; the subiculum becomes located on one side of the hippocampal sulcus and the dentate gyrus on the other side. Eventually, the hippocampus (cornu ammonis) curves around the hippocampal fissure, and the dentate gyrus lies within the concave aspect of the curve.

The outer gray substance of the primordium of the archeopallial cortex ends within the bulging prominence between the hippocampal fissure and the choroid fissure, leaving the white matter, called the **alveus**, exposed along the edge of the hippocampus adjacent to the epithelial cells of the ependyma. These fibers join to form the fimbria of the fornix. With the downward and forward growth of the temporal lobe, the hippocampal fissure and parts associated with it extend from the interventricular foramen to the end of the inferior horn of the lateral ventricle.

**Corpus Striatum.** The corpus striatum appears as a thickening in the floor of the telencephalon between the optic stalk and the interventricular foramen, adjacent to the thalamus (Figs. 11-12; 11-14; 11-20; 11-21). By the second month it has increased in size and bulges from the floor of the lateral ventricle into the ventricular lumen, extending as far as the occipital pole of the primitive hemisphere.

As the expansion of the cerebral hemispheres gradually covers the diencephalon, a part of the corpus striatum is carried into the lateral ventricular wall and downward into the roof of the inferior horn of the lateral ventricle as the tail of the caudate nucleus. During the fourth and fifth months, the corpus striatum is invaded and incom-

pletely subdivided by large numbers of fibers of the internal capsule into two masses: an inner or dorsomedial part adjacent to the ventricle, the **caudate nucleus**, and an outer part, ventrolateral to the fibers of the internal capsule, the **lentiform nucleus** (Fig. 11-21). This latter nucleus develops into the larger **putamen** laterally and the smaller **globus pallidus** medially.

**The Neopallium.** The neopallium, or non-olfactory part of the cerebral cortex, forms the greater part of the hemisphere. Early in development its cavity is the primitive **lateral ventricle**. This is enclosed by a thin wall of neural tissue from which the cortex of the hemisphere is derived, and it expands in all directions but especially dorsally and caudally. By the third month the hemispheres cover the diencephalon; by the sixth month they overlap the midbrain; and by the eighth month they reach the hindbrain. The median lamina uniting the two hemispheres does not share in their expansion and remains as the thin roof of the third ventricle. Thus, between the hemispheres there develops a deep cleft, the forerunner of the **longitudinal cerebral fissure**. The cleft becomes occupied by a septum of mesodermal tissue that constitutes the primitive **falx cerebri**. As the cerebral hemispheres expand, each lateral ventricle is gradually drawn outward onto three prolongations that represent the future anterior, inferior, and posterior horns.

The part of the wall along the medial border of the primitive lateral ventricle, which is immediately continuous with the roof plate of the diencephalon, lies over the primitive interventricular foramen and extends caudally. This border remains thin and has an ependymal or epithelial character. It is invaginated into the medial wall of the lateral ventricle to form the **choroid fissure** (Figs. 11-14; 11-22). Mesodermal tissue from the outer surface of the hemisphere, the rudiment of the pia mater, spreads into the fissure between the two layers of the ependyma to form the rudiment of the **tela choroidea**. The blood vessels accompanying the mesoderm form the **choroid plexus**, which almost completely fills the cavity of the ventricle for several months (Figs. 11-20; 11-21). The tela choroidea, lying over the roof of the diencephalon, also invaginates the thin epithelial covering to form the choroid plexus of the third ventricle.

As described previously, the medial wall

Embryonic ages: early, mid, and latter part of the sixth week. (From W. J. Hamilton and H. W. Mossman, *Human Embryology*, 4th ed., Williams and Wilkins, Baltimore, 1972.)

**Fig. 11-21.** Frontal section through the left cerebral hemisphere of a 73-mm human fetus (fourth month). Observe the developing ventricular system and the corpus striatum. (From W. J. Hamilton, and H. W. Mossman, *Human Embryology*, 4th ed., Williams and Wilkins, Baltimore, 1972.)

of the cerebral hemisphere becomes folded into the cavity of the lateral ventricle and develops as the rudiment of the hippocampal formation. Growth of the remaining cerebral cortex is so great that the structure is thrown into folds or convolutions (gyri) between which are formed the sulci or fissures. Additionally, groups of nerve fibers pass from one hemisphere to the other, forming the commissures.

**The Commissures.** The development of the **posterior commissure** was mentioned in the section describing the embryology of the diencephalon. The other commissures interconnecting the two hemispheres are the large **corpus callosum**, the **anterior commissure**, and the small **commissure of the fornix**, which all arise from the lamina terminalis (Fig. 11-22). At about the fourth month a small thickening appears in this lamina, immediately in front of the interventricular foramen. The lower part of this thickening soon becomes constricted, and fibers grow into it to form the anterior commissure. These fibers interconnect the two olfactory bulbs and certain other paleopallial structures of the two sides, such as the piriform and prepiriform regions and the amygdaloid

nuclei. The upper part continues to grow caudally with the hemispheres and is invaded by two sets of fibers. Transverse fibers, extending between the two cerebral hemispheres, pass into its dorsal part and become differentiated as the corpus callosum. Longitudinal fibers from the hippocampus pass into the ventral part of the lamina terminalis, and arching over the thalamus to the mammillary bodies, develop into the fornix. The anterior portion between the corpus callosum and fornix is not invaded by commissural fibers and becomes the **septum pellucidum**.

**Sulci and Gyri.** The outer surface of the cerebral hemisphere is at first smooth. Later it exhibits a number of convolutions, or gyri, that are separated from each other by sulci, which appear during the sixth or seventh month of fetal life. The term **complete sulcus** is applied to grooves that involve the entire thickness of the cerebral wall and thus produce corresponding eminences in the ventricular cavity. The other sulci affect only the superficial part of the wall and therefore leave no impressions in the ventricle.

The complete sulci are the **choroidal** and **hippocampal**, which have already been de-

FIG. 11-22. Median sagittal section of brain of human embryo of four months. (Marchand.)

scribed; the **calcarine**, which produces the swelling known as the **calcar avis** in the posterior horn of the ventricle; and the **collateral sulcus**, with its corresponding eminence in the ventricular cavity. The **central sulcus** (the fissure of Rolando<sup>1</sup>) develops in two parts; the **intraparietal sulcus**, in four parts; and the **cingulate sulcus**, in two or three parts. The **lateral cerebral** (or Sylvian) **sulcus** differs from all the other sulci in its mode of development. It appears toward the end of the third month as a depression, the **Sylvian fossa**, on the lateral surface of the hemisphere (Fig. 11-23). The floor of this fossa becomes the **insula**, and its adherence to the subjacent corpus striatum prevents this part of the cortex from expanding at the same rate as the portions that surround it. The neighboring parts of the hemisphere, therefore, gradually grow over and cover the insula, constituting the **temporal, parietal, frontal, and orbital opercula** of the adult brain. The frontal and orbital opercula are the last to form, but by the end of the first year after birth, the insula is completely submerged. The sulci separating the opposed margins of the opercula constitute the adult lateral cerebral sulcus.

#### Development of the Autonomic Nervous System

The autonomic nervous system consists of **sympathetic** and **parasympathetic** divisions. It is a two-motor neuron system, of which

the cell body of the first, or **preganglionic**, neuron lies within the substance of the brain or spinal cord, while the cell body of the second, or **postganglionic**, neuron is located more peripherally in one of the autonomic ganglia outside the central nervous system.

**SYMPATHETIC NERVOUS SYSTEM.** The cell bodies of the preganglionic neurons in the sympathetic division of the autonomic nervous system are located in the lateral gray matter of the spinal cord in a column extending from the first thoracic segment through the second lumbar segment. Occupying a position between the afferent groups of the dorsal horn and the somatic efferent groups of the ventral horn, the preganglionic

FIG. 11-23. Outer surface of cerebral hemisphere of human embryo of about five months.

<sup>1</sup>Luigi Rolando (1773-1831): An Italian anatomist (Turin).

sympathetic neurons develop axons that grow out through the ventral roots with the somatic motor fibers. Eventually these preganglionic elements leave the spinal nerves by way of the white rami communicantes to synapse with postganglionic sympathetic neurons within the ganglia of the **sympathetic trunk** or in the other outlying collateral ganglia found in the abdomen.

**Sympathetic Ganglia.** Most investigators today believe that the ganglion cells that form the sympathetic ganglia are derived from the **neural crest**. These cells commence migrating along the dorsal roots of the spinal nerves during the fifth prenatal week, and they eventually form segmentally paired neuronal groups in the embryonic thoracic region dorsolateral to the aorta. Soon the fibers grow between the masses of cells to form the sympathetic chains. Other ganglion cells grow from the cervical and lumbar regions of the neural crest to form the cervical and lumbosacral ganglia. Certain sympathetic ganglion cells migrate beyond the sympathetic trunk to form ganglia adjacent to the branches of the abdominal aorta. These outlying **collateral ganglia** develop shortly after those of the sympathetic trunk and include the **celiac, superior mesenteric, and inferior mesenteric ganglia**. The nerve fibers of the postganglionic sympathetic neurons are either unmyelinated or surrounded by very thin myelin sheaths.

**PARASYMPATHETIC NERVOUS SYSTEM.** The parasympathetic nervous system consists of **preganglionic** nerve cells that arise in the visceral efferent nuclei of the brain, and their axons grow out of the brain by way of the oculomotor, facial, glossopharyngeal, and vagus nerves. Additionally, other preganglionic parasympathetic neurons develop in the lateral gray column of the second, third, and fourth sacral segments and leave the spinal cord in the ventral roots of the sacral nerves. The oculomotor, facial, and glossopharyngeal parasympathetic neurons course to ganglia in the orbit, deep face, and lower jaw, from which **postganglionic** parasympathetic fibers course to the viscera in the head. The vagus nerve descends to supply preganglionic fibers to terminal ganglia within or near the viscera of the neck, thorax, and abdomen. Sacral parasympathetic fibers grow as far as terminal ganglia in the lower part of the gastrointestinal tract and in the pelvic organs.

**Parasympathetic Ganglia.** The precise

origin of the ganglion cells that form the **ciliary, pterygopalatine, submandibular, and otic** ganglia of the head is still not completely understood. Some believe that the ganglion cells migrate from the trigeminal ganglion along the developing divisions of the trigeminal nerve. Others feel that all the cells are derived from the central nervous system and migrate along the specific cranial nerves that carry the preganglionic fibers. Still other investigators feel that the parasympathetic ganglia in the head receive cells not only from the sensory ganglion of the trigeminal nerve, but also from the geniculate ganglion of the facial nerve and the inferior ganglion of the glossopharyngeal nerve.

The origin of the postganglionic neurons that synapse with the preganglionic vagal fibers is also uncertain. It has been proposed that they derive from several sources, including the ganglia of the vagus nerve, and from the central nervous system by migrating along the vagal trunks. The ganglion cells associated with the sacral parasympathetic fibers are thought to arise from the neural crest, which forms adjacent to the sacral segments of the neural tube.

### *Development of the Cranial Nerves*

The development of the olfactory, optic, and vestibulocochlear nerves is described in more detail in Chapter 13. The pattern of development of the other cranial nerves is quite similar to that of the spinal nerves. The cranial sensory or *afferent* nerves are derived from cells in the ganglion rudiments of the neural crest. Evidence from research in lower animal forms also indicates that ectodermal thickenings that overlie the ganglia make some contribution to the formation of the sensory ganglia of the **trigeminal, facial, glossopharyngeal, and vagus** nerves. These have been called **epibranchial placodes**. The central processes of these ganglion cells grow into the brain and form the sensory elements in the roots of the nerves, while the peripheral processes extend distally to their sensory fields of distribution. In considering the development of the medulla oblongata, it appears that the **tractus solitarius** (Fig. 11-10) is derived from the fibers that grow inward from the ganglion rudiments of the glossopharyngeal and vagus nerves, and that it is the homologue of the **oval bundle** in the cord, which has its origin in the dorsal nerve roots. During the development of the bulbar

**Fig. 11-24.** Reconstruction of the nervous system in a 10-mm human embryo during the fifth prenatal week (from the studies of G. L. Streeter). Note the developing cranial and spinal nerves. (Taken from B. M. Patten, *Human Embryology*, 3rd ed., McGraw-Hill, New York, 1968.)

part of the accessory nerve and the hypoglossal nerve, strands of ganglion cells extend along the rootlets of these cranial nerves. These are derived from an embryonic sensory ganglion, known as **Froriep's<sup>2</sup> ganglion**, which develops between the jugular ganglion of the vagus and the first cervical ganglion (Fig. 11-24). Most of Froriep's ganglion disappears in the adult, although occasionally ganglion cells can be observed

along the course of the accessory and hypoglossal nerves.

The motor or efferent components of the cranial nerves arise as outgrowths of the neuroblasts that are situated in the basal laminae of the midbrain and hindbrain. In contrast to the spinal motor nerve rootlets that develop from the basal lamina in single sets at each segmental level, the motor rootlets of the cranial nerves form two sets as they emerge from the brainstem. One group of rootlets develops from the medial and the

**Fig. 11-25.** Four stages in the development of the brain and cranial nerves (adapted from various sources, but principally from the studies of G. L. Streeter). A, 20-somite stage (about three and one-half weeks); B, 4-mm stage (about four weeks); C, 8-mm stage (about four and one-half weeks); D, 17-mm stage (about six and one-half weeks). The cranial nerves are indicated by the appropriate Roman numerals. Abbreviations: Hy., hyoid arch; Md., mandibular arch. (Taken from B. M. Patten, *Human Embryology*, 2nd ed., McGraw-Hill, New York, 1953.)

other from the lateral parts of the basal lamina. From the medial part of the basal lamina develop the somatic efferent fibers of the oculomotor, trochlear, abducent, and hypoglossal nerves that supply the striated musculature formed from the somites (Fig. 11-24). The lateral part of the basal lamina forms the accessory nerve and the branchial motor fibers of the trigeminal, facial, glossopharyngeal and vagus nerves that supply the voluntary musculature formed from the branchial arches (Figs. 11-24; 11-25).

## Gross Anatomy of the Central Nervous System

The central nervous system, divided for convenience of description into the **spinal cord** (or medulla spinalis) and **brain** (or encephalon), is a single, continuous organ system from which also are derived the 12 pairs of cranial nerves and the 31 pairs of spinal nerves (Fig. 11-26). The cranial and spinal

nerves, along with their ganglia and those of the autonomic nervous system, constitute the **peripheral nervous system**. The central nervous system functions to integrate information that it receives from the environment by way of **receptors** and the **sensory nerves**. Its reactions are transmitted to the **effectors** through the **motor nerves**.

The spinal cord and brain are composed of groups of neuron cell bodies, which together with their dendritic processes form the **gray substance**. Elongated processes, frequently myelinated and extending from the nerve cells, collect in bundles to form the **white substance** and the **tracts**. Enmeshed among the neurons and the processes are large numbers of neuroglial cells and capillaries that maintain the appropriate chemical environment and provide the nutrients necessary for proper neuronal metabolism.

Because the internal neuroanatomy of the central nervous system is a subject more appropriately handled in specialized textbooks and taught as a discipline separate from gross anatomy, most of the remainder

**FIG. 11-26.** The dorsal aspect of the spinal cord exposed within the vertebral canal. The spinous processes and the laminae of the vertebrae have been removed and the dura mater has been opened longitudinally. (Redrawn after Sobotta.)

of this chapter deals with the external and gross anatomy of the spinal cord and brain. Reference is made to the internal anatomy of the central nervous system on those occa-

sions when it will lead to a better understanding or description of the external form.

The principal subdivisions of the central nervous system include the **spinal cord**,

**rhombencephalon** (hindbrain), **mesencephalon** (midbrain), and **prosencephalon** (forebrain). The rhombencephalon consists of the **myelencephalon** (medulla oblongata) and the **metencephalon** (pons and cerebellum), while the prosencephalon includes the **diencephalon** (thalamus and hypothalamus) and **telencephalon** (cerebral hemispheres).

## SPINAL CORD

The **spinal cord** (*medulla spinalis*) is the elongated, nearly cylindrical part of the central nervous system that lies within most of the vertebral canal (Fig. 11-26). The diameter of the spinal cord in the midthoracic region is about 1 cm, but it is significantly greater at the lower cervical and midlumbar levels. Its average length in the male is about 45 cm, and in the female, from 42 to 43 cm, while its weight amounts to about 30 gm. The spinal cord extends from the upper border of the atlas, where it is continuous through the foramen magnum with the medulla oblongata of the brain stem, to the lower border of the first or upper border of the second lumbar vertebra, where it tapers to a point, forming the **conus medullaris** (Figs. 11-27; 11-30).

The position of the spinal cord varies somewhat with the movements of the vertebral column, being drawn upward slightly when the column is flexed. The degree to which the spinal cord fills the vertebral column also varies at different periods of life. Until the third prenatal month the spinal cord is as long as the vertebral column, but from this stage onward the vertebral column elongates more rapidly than the spinal cord. By the end of the fifth prenatal month, the spinal cord terminates at the base of the sacrum, and at birth it ends at about the third lumbar vertebra. It gradually recedes during childhood until it reaches the adult position (Fig. 11-5). Surrounding the spinal cord are three protective membranes called **meninges**—the **dura mater**, the **arachnoid**, and the **pia mater** (Figs. 11-29; 11-31). Between the latter two is found the **cerebrospinal fluid**. These membranes are described more completely elsewhere in this chapter.

The **filum terminale** is a delicate filament that continues down the vertebral canal from the apex of the conus medullaris to the first segment of the coccyx (Figs. 11-26; 11-27; 11-30). It is approximately 20 cm in length. Its upper 15 cm, contained within the

**Fig. 11-27.** The cauda equina of the spinal cord showing the conus medullaris, the filum terminale internum, and the filum terminale externum. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Vol. 3, 9th ed., Urban and Schwarzenberg, Munich, 1975.)

tubular sheath of the dura mater and surrounded by the nerves of the cauda equina, is called the **filum terminale internum**. The lower part, the **filum terminale externum**, is closely invested by the dura mater to which it adheres. Extending beyond the apex of the sheath, it finally attaches to the dorsal part of the first coccygeal segment (Fig. 11-27). The filum consists mainly of fibrous tissue continuous with the pia mater. A few nerve fibers adherent to the outer surface probably represent rudimentary second and third coccygeal nerves. The central canal of the spinal cord continues down into the filum for 5 or 6 cm.

### Relationships and Form of the Spinal Cord

**VERTEBRAL COLUMN AND CAUDA EQUINA.** It was just stated that the neural substance of the adult spinal cord does not occupy the entire length of the vertebral canal, as was the case during the third month of prenatal development, because the vertebral column grows at a faster pace than the spinal cord. Because the cord is continuous with the developing brain, and thereby firmly anchored rostrally, this differential growth pattern causes the spinal cord to be drawn upward in the vertebral canal. There results a great intravertebral lengthening of the lumbar and sacral nerve roots because they still emerge from the vertebral column through their segmentally appropriate intervertebral foramina below (Fig. 11-28). These caudally placed nerve roots are directed in a progressively more oblique manner, so that they pass almost vertically downward within the dura mater for some distance before reaching their foramina of exit. The resulting collection of rootlets beyond the termination of the neural substance of the cord is called the **cauda equina** (Figs. 11-26 to 11-28).

**EPIDURAL SPACE.** The dimensions of the vertebral canal within the spinal column are considerably greater than the diameter of the enclosed spinal cord and its meningeal coverings. This permits the required movements of the cord during flexion and extension of the vertebral column without a resultant spinal contusion or compression. Between the bony inner wall of the vertebral canal and the outer surface of the dura mater is found the **epidural space**, and this is loosely packed with strands of **epidural fat**. Closely adhering to the wall of the vertebral canal are the internal vertebral venous plexuses. Additionally, fine dorsal and ventral epidural branches of the spinal arteries ramify within the epidural fat to supply the vertebrae and the external surface of the spinal dura mater.

**ENLARGEMENTS OF THE CORD.** The spinal cord is slightly flattened dorsoventrally and its diameter is increased by enlargements in two regions: cervical and lumbar (Fig. 11-30). The **cervical enlargement** extends from about the fifth cervical to the second thoracic vertebra, its maximum circumference (about 38 mm) being at the level of the sixth pair of cervical nerves. It corresponds to the origin of the large nerves that supply the upper limbs. The **lumbar enlargement** be-

**Fig. 11-28.** Diagram showing the relationship of the spinal cord segments and the level of emergence of the spinal nerves to the bodies and spinous processes of the vertebrae. (From W. Haymaker and B. Woodhall, *Peripheral Nerve Injuries*, 2nd ed., W. B. Saunders, Philadelphia, 1953.)

**Fig. 11-29.** The dura mater has been opened to reveal the dorsal aspect of the spinal cord. Note that the thin arachnoid membrane has been left intact in the upper part of the exposure. (From P. Thorek, *Anatomy in Surgery*, 2nd ed., J. B. Lippincott, Philadelphia, 1962.)

gins at the level of the ninth thoracic vertebra and reaches its maximum circumference (about 33 mm) opposite the last thoracic vertebra, after which it tapers rapidly into the conus medullaris. These vertebral levels correspond to the sites of attachment of nerve roots that extend from the first lumbar to the third sacral segment. From these segments arise the nerves that supply the lower limb.

**FISSURES AND SULCI.** After removal of the meningeal coverings, especially the pia mater, the surface of the spinal cord is marked by several longitudinal furrows. Two of these, the **anterior median fissure** and the **posterior median sulcus**, nearly divide the spinal cord longitudinally into symmetrical right and left halves. The two sides of the cord remain interconnected, however, by commissural bands of gray and white matter. Within the gray commissural bands is located the central canal. The dorsal surface of the cord also shows a **posterolateral sulcus**, as well as a **posterior intermediate sulcus** (Figs. 11-30 to 11-32).

**Anterior Median Fissure.** The anterior median fissure traverses the entire extent of the anterior surface of the spinal cord along its midline (Figs. 11-30 to 11-32). It penetrates an average depth of about 3 mm, being somewhat deeper more caudally. It contains adjacent folds of pia mater and the floor of the fissure is formed by a band of transversely crossing white fibers, the **ventral**

**Fig. 11-30.** Anterior and posterior diagrams of the spinal cord.

**FIG. 11-31.** The dorsal aspect of the spinal cord. In the lower region the dura mater is intact, while in the upper region all of the meningeal coverings have been removed. (After Sobotta.)

**white commissure.** This commissure is perforated by branches of the anterior spinal vessels, which serve the central part of the spinal cord.

**Posterior Median Sulcus.** The posterior median sulcus is a shallow groove from which a thin sheet of neuroglial tissue, the **posterior median septum**, penetrates more than half way into the substance of the cord, effectively separating the dorsal portion into right and left halves (Fig. 11-32). This septum varies in depth from 4 to 6 mm, but dimin-

ishes considerably in the lower part of the spinal cord.

**Posterolateral Sulcus.** The posterolateral sulcus is a longitudinal furrow located on each side of the posterior median sulcus along the line of attachment of the dorsal roots of the spinal nerves (Figs. 11-30; 11-32). Between the posterolateral sulcus and the posterior median sulcus on each side is found the **posterior funiculus**. Together the posterior funiculi are frequently called the posterior white columns of the spinal cord.

Fig. 11-32. Transverse section of the spinal cord in the midthoracic region.

**Posterior Intermediate Sulcus.** The posterior intermediate sulcus is a groove found in the upper thoracic and cervical regions of the spinal cord and interposed between the posterior median sulcus and the posterolateral sulcus along the posterior funiculus (Figs. 11-30; 11-32). It marks the line of separation between two ascending large tracts of white nerve fibers, the more medially located **fasciculus gracilis**, and the **fasciculus cuneatus** found more laterally.

Another less prominent groove, the **anterolateral sulcus**, is sometimes described as being in relationship to the emerging ventral roots (Figs. 11-30; 11-32). The relationship is frequently indistinct, however, because the ventral rootlets arise in bundles and not in a linear series and they emerge over an area of some slight width. The white matter of the spinal cord between the posterolateral sulcus and the anterior median fissure is divided into a **lateral funiculus** and an **anterior funiculus** by the ventral roots (Fig. 11-32). In the upper part of the cervical spinal cord, in addition to the dorsal and ventral roots, a series of nerve roots passes outward through the lateral funiculus. These unite to form the **spinal portion of the accessory nerve (XI)**, which ascends through the foramen magnum to enter the cranial cavity. There it contributes the motor fibers of the eleventh

cranial nerve that supply the sternocleidomastoid and trapezius muscles.

**SEGMENTS OF THE SPINAL CORD.** Thirty-one pairs of spinal nerves originate from the spinal cord, each with a **ventral** (or anterior) **root** and a **dorsal** (or posterior) **root**. The pairs are grouped as follows: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal (Fig. 11-28). The cord itself also is divided for convenience of description into cervical, thoracic, lumbar, and sacral regions to correspond with the nerve roots. It is customary also to speak of the part of the cord giving rise to each pair of nerves as a **spinal segment** or **neuromere**, although the distinguishing marks, except for the roots, are not retained after embryonic life. Arbitrarily defined, each spinal segment is considered to extend from the uppermost filament of one root to the uppermost filament of the next root. The segments vary in their extent along the cord; in the cervical region they average 13 mm and in the midthoracic region, 26 mm, whereas their length diminishes rapidly in the lumbar and sacral regions from 15 to 4 mm.

**SPINAL NERVE ROOTS.** Each spinal nerve has two roots: a **dorsal** (or posterior) **root**, also called the sensory root because its fibers transmit impulses to the cord, and a **ventral** (or anterior) **root**, also called the motor root

because its fibers carry impulses outward from the cord to muscles and other structures.

**Dorsal (Posterior) Roots.** The dorsal roots are attached in linear series along the posterolateral sulcus of the cord, and each segmental root consists of six or eight **rootlets** (*fila radicularia*) (Fig. 11-31). They contain the central processes of spinal ganglion cells whose peripheral processes extend outward to the sensory endings in the skin, muscles, tendons, and viscera. The rootlets are divided into two groups as they enter the cord: a *medial bundle* containing mainly large myelinated fibers and a *lateral bundle* containing finely myelinated and unmyelinated fibers. Arising from the spinal ganglion cells, the roots are accompanied by delicate radicular branches of the spinal arteries and veins. Within the vertebral canal, the dorsal roots penetrate the dura mater and the underlying arachnoid membrane and then course for varying distances, depending on their segmental level, within the subarachnoid space before entering the spinal cord at the root-cord junction.

**Ventral (Anterior) Roots.** The ventral roots emerge from the spinal cord in two or three irregular rows of rootlets spread over a strip about 2 or 3 mm wide. Like the dorsal roots, the ventral roots are usually accompanied by branches of the spinal vessels. They course within the subarachnoid space prior to becoming surrounded by the tubular prolongations of the dura mater and arachnoid, which encase the spinal nerves and the dorsal root ganglia at the intervertebral foramina. The ventral roots join the dorsal roots to form the mixed spinal nerve at each segmental level. The ventral roots contain the axons of the cells in the anterior and lateral cell columns of the central gray matter of the cord.

### **Arterial Blood Supply of the Spinal Cord**

The basic pattern of the arterial blood supply to the spinal cord consists of three longitudinally coursing vessels that arise just rostral to the cervical region of the cord and descend on its surface as far as the conus medullaris, and numerous feeder arteries and radicular vessels that gain entrance to the vertebral canal segmentally by coursing through the intervertebral foramina with the spinal nerves (Figs. 11-33 to 11-

36). Anastomoses between the longitudinally oriented and the segmentally derived vessels occur on the surface of the spinal cord and result in the formation of a rich vascular plexus from which medullary vessels penetrate the substance of the cord to reach both the white and gray matter. Vessels that penetrate the spinal cord substance are thought, for the most part, to be end arteries and, therefore, they do not anastomose further. Although there is significant variation with respect to the segmental levels at which the feeder vessels enter the vertebral canal, there is a general consistency in the overall vascular pattern, namely, that longitudinally oriented vessels descending from above are supplemented by branches from the medially coursing spinal arteries at varying segmental levels.

### **LONGITUDINAL ARTERIES SUPPLYING THE SPINAL CORD**

There are usually three longitudinally oriented spinal arteries. These are a single **anterior spinal artery**, which descends in the anterior median fissure, and two **posterior spinal arteries**, which descend along or near the posterolateral sulci of the spinal cord (Figs. 11-33 to 11-36).

**ANTERIOR SPINAL ARTERY.** The anterior spinal artery is sometimes called the *anterior median longitudinal artery of the spinal cord*. It usually forms rostrally from the junction of two anterior spinal branches, one derived from each of the two vertebral arteries (Figs. 11-33; 11-34). The union of these two vessels generally occurs intracranially at or near the midline on the anterior aspect of the medulla oblongata at about the level of the olivary nuclei. From this site, the anterior spinal artery descends without interruption to the tip of the conus medullaris, lying just ventral to the anterior median fissure. Slightly dorsal and to one side of the artery courses the anterior median longitudinal venous trunk of the spinal cord (Suh and Alexander, 1939). Frequently the anterior spinal artery is duplicated in the cervical cord region because of an incomplete fusion of its two fetal precursors (Aminoff, 1976). Occasionally, one of the paired vertebral branches is much smaller or even absent, and at other times two or more very slender spinal vessels may branch from one of the vertebral arteries to unite with a large

**FIG. 11-33.** Diagrammatic representation of the anterior spinal artery. Note that the anterior feeder vessels are derived from the intercostal and vertebral arteries, as well as from spinal branches from vessels coming off the thyrocervical and costocervical trunks. Rostrally, the anterior spinal artery is formed from anterior spinal branches derived from each vertebral artery. (After Sobotta.)

**Fig. 11-34.** The vascular pattern of the anterior spinal artery and the anterior medullary feeder arteries in three adult human specimens. The numbers within the figure indicate the approximate diameters of the different vessels in micrometers. V.A., vertebral artery; S.I., superior intercostal artery. (From G. F. Dommissie, *The Arteries and Veins of the Human Spinal Cord from Birth*, Churchill-Livingstone, Edinburgh, 1975.)

branch from the other side (Tveten, 1976). Along its course the anterior spinal artery varies considerably in its diameter, but its caliber is consistently larger in the cervical and lower thoracic regions. Along the mid-portion of the thoracic spinal cord (i.e., between T3 and T9), the vessel is quite slender (0.35 to 0.50 mm), and this region of the cord has been considered a *vulnerable zone* with

respect to its circulation (Dommissie, 1975). At the conus medullaris and along the filum terminale, the anterior spinal artery is reduced in size to a tiny vessel that frequently communicates by anastomotic branches with the posterior longitudinal arteries.

The anterior spinal artery is reinforced at a number of segmental levels by **feeder arterial branches** from the segmental arteries

**FIG. 11-35.** The arterial blood supply of the spinal cord is derived from anterior and posterior spinal arteries, which usually branch from the vertebral artery, as well as from radicular and medullary feeder branches coming from segmental vessels. (Redrawn after Netter.)

that enter the vertebral canal, accompanying the spinal nerves and their roots (Fig. 11-34). The largest of these feeder vessels invariably increases the diameter of the anterior spinal artery beyond its point of junction.

**POSTERIOR SPINAL ARTERIES.** The two posterior spinal arteries are sometimes called the *paired posterolateral longitudinal arterial trunks of the spinal cord*. On each side the vessel usually originates directly from the intracranial part of the vertebral

artery, somewhat lower than the origins of the branches that unite to form the anterior spinal artery (Figs. 11-35; 11-36). At times the posterior spinal arteries do not arise directly from the vertebral arteries, but from their posterior inferior cerebellar branches instead. Each vessel descends on the posterior surface of the spinal cord along the posterolateral sulcus in close relationship to the line of entrance of the dorsal roots. They are smaller in diameter and more irregular than

**Fig. 11-36.** The vascular pattern of the posterior spinal arteries and the posterior medullary feeder arteries in three human specimens (15 months, 22 years, 15 years). The numbers within the figures indicate the approximate diameters of the different vessels in micrometers. V.A., vertebral artery; D.C., deep cervical artery; S.I., superior intercostal artery. (From G. F. Domisse, *The Arteries and Veins of the Human Spinal Cord from Birth*, Churchill-Livingstone, Edinburgh, 1975.)

the anterior spinal artery and communicate by many anastomosing channels with incoming segmental arteries and across the midline with each other. To some extent the pattern thus formed resembles an embryonic plexus, but usually the longitudinal continuity of the vessels can be discerned throughout the length of the cord (see Fig.

11-37). Along the conus medullaris, the posterior spinal arteries communicate freely with branches from the anterior spinal artery to form what is frequently called the **cruciate anastomosis** of the conus medullaris. Throughout its course, each posterior spinal artery gives off branches that penetrate the cord to supply the white matter of

**FIG. 11-37.** A posterior view of the cervical spinal cord showing an arterial injection of the posterior spinal arteries, certain radicular arteries, several larger vessels along the roots which are posterior medullary feeder arteries, and the anastomotic network of the dorsal cord. (Maillot and Koritke, 1970.)

the posterior columns, the dorsal gray matter, and the superficial dorsal aspect of the lateral columns.

#### SEGMENTAL ARTERIES SUPPLYING THE SPINAL CORD

The spinal cord receives segmental arteries bilaterally at every intervertebral level and these vessels enter the spinal canal by way of the intervertebral foramina. In the upper three to five *cervical* segments, they are medially coursing branches of the vertebral artery, whereas in the lower cervical region, they may be derived from the ascending cervical branch of the inferior thyroid artery or from the deep cervical branch of the costocervical trunk (Fig. 11-35). In the *thoracic* region, the segmental vessels sup-

plying the spinal cord come from the posterior intercostal arteries, which stem directly from the posterior aspect of the thoracic aorta. In the *lumbar* region, they branch from the lumbar arteries, while the segmental arteries supplying the *sacral* region usually stem from the lateral sacral arteries or, less commonly, from the middle sacral artery (Gillilan, 1958).

#### RADICULAR AND MEDULLARY FEEDER BRANCHES OF THE SEGMENTAL ARTERIES.

As they enter the intervertebral foramina, the segmental spinal arteries at every level give rise to the true **dorsal and ventral radicular branches**, which course with and supply the dorsal and ventral roots. Additionally, at certain of the vertebral levels, **medullary feeder branches** arise from the segmental spinal arteries to join the anterior and posterolateral longitudinally coursing spinal arteries (Figs. 11-34 to 11-38). These reinforce the circulation descending from above and are most important in maintaining an appropriate level of blood supply to the cord. The medullary feeder arteries vary both in number and in the levels at which they arise in different individuals.

**Anterior Medullary Feeder Arteries.** There is an average total of eight anterior medullary feeder arteries (both sides included in the total) that enter the vertebral canal segmentally to join the anterior (longitudinal) spinal artery (Fig. 11-34); however, the number varies from 2 to 17 in different individuals (Dommissé, 1975). Their diameter varies from 0.2 to 0.8 mm. One especially large (1.0 to 1.3 mm) and important vessel, the **great anterior medullary artery** (or artery of Adamkiewicz<sup>1</sup>), which reinforces the circulation to the lumbar enlargement, usually enters the vertebral canal at the lower thoracic or upper lumbar level. This vessel, however, has been observed to enter as high as the seventh thoracic and as low as the fourth lumbar level. It is a unilateral artery and in 77% of the specimens studied it entered the spinal cord from the left side (Dommissé, 1975).

Three anterior medullary feeder arteries (range one to six) join the ventral spinal artery in the *cervical* region. The largest of these is most frequently at the fifth or sixth

<sup>1</sup>Albert Adamkiewicz (1850-1921): A Polish experimental pathologist (Krakow).

**FIG. 11-38.** Diagram of the arterial vascular pattern of a spinal cord segment. Note the difference between the medullary feeder branches and the radicular branches of the segmental spinal arteries. (From W. F. Windle, ed., *The Spinal Cord and Its Reaction to Injury*, Marcel Dekker, New York, 1980.)

cervical level. The thoracic region receives an average of three feeder arteries (range one to five), and the lumbar spinal cord, an average of two feeder vessels.

**Posterior Medullary Feeder Arteries.** The posterior medullary feeder arteries are smaller in diameter but more numerous and more evenly distributed than the anterior (Fig. 11-36). In the series of dissections reported by Domisse (1975), the average total of posterior feeder arteries observed (both sides included) was 12, with a range from 6 to 25. Gillilan (1958) reported a range of 10 to 20 vessels, while Tveten (1976) found a range of 14 to 25. Thus, in the cervical region, an average number of three posterior medullary feeder arteries can be expected, with the highest incidence of vessels found at vertebral levels C6 to C8. An average of five posterior feeder vessels has been found between spinal segments T2 to T9, and four vessels between T10 and S5. The diameter of the posterior medullary feeder arteries ranges from 0.05 to 0.35 mm.

#### INTRAMEDULLARY ARTERIES OF THE SPINAL CORD

Most of the gray and white substance of the spinal cord receives arterial blood by way of branches from the anterior and posterior spinal arteries. A small amount of the parenchyma of the cord, however, is supplied by the five radicular branches of the segmental spinal arteries that course intimately with the dorsal and ventral roots. Some of these latter vessels penetrate the surface of the cord and accompany the roots through the root-cord junction (Figs. 11-38; 11-39).

**INTRAMEDULLARY BRANCHES FROM THE ANTERIOR SPINAL ARTERY.** The anterior spinal artery gives rise to many short and straight branches that frequently stem at right angles to the main trunk and course posteriorly through the anterior median fissure to reach the anterior commissural region of the spinal cord. These are called **sulcal (or central) arteries**, and most arise singly (Fig. 11-38). Reaching the cord at the depth of the fissure,

**Fig. 11-39.** Diagram of a cross section of the spinal cord showing the regions supplied by the various intramedullary arteries. A, Region of distribution of the sulcal (central) artery; D, region supplied by the penetrating arteries from the lateral and ventral pial plexus; ad, the region that may be supplied by either the sulcal artery or the lateral and ventral penetrating arteries; B, the region supplied by the penetrating arteries from the posterior pial plexus; ob, the region that may be supplied by either the sulcal or the posterior penetrating arteries. (L. A. Gillilan, 1958.)

each sulcal artery turns to the left or right but does not bifurcate to supply both sides. Successive sulcal arteries frequently turn alternately, but occasionally consecutive vessels turn to the same side. The number of sulcal arteries supplying each segment varies from five to nine, being more numerous in those segments that form the spinal cord enlargements. Counts ranging from 184 to 228 sulcal arteries (average 210) for all 31 segments of the cord have been reported (Tvetan, 1976).

In addition to the sulcal branches, the anterior spinal artery gives rise to a number of delicate **coronal arteries**, which course laterally around the outer surface of the cord (Fig. 11-38). They help to form a superficial pial plexus and they anastomose with each other and with superficial branches from the posterior spinal arteries. From the coronal arteries and the pial plexus, penetrating branches enter the white matter of the ventral and lateral columns.

The sulcal arteries and the penetrating branches from the coronal arteries together supply the anterior two-thirds of the spinal cord (Fig. 11-39). The anterior gray column, the base of the posterior gray column, and the deeper portions of the white matter in

the anterior and lateral columns are supplied by sulcal vessels, while the more superficial regions of white substance are supplied by branches from the coronal vessels and the surface pial plexus.

**INTRAMEDULLARY BRANCHES FROM THE POSTERIOR SPINAL ARTERIES.** The two posterior spinal arteries, coursing in the posterolateral sulci, give off penetrating branches that supply the posterior one-third of the spinal cord (Fig. 11-39). At each level, some of these vessels accompany the fibers of the dorsal roots into the posterior gray substance of the dorsal horn. Entering the spinal cord, they branch at an acute angle and quickly subdivide into precapillary and capillary vessels (Gillilan, 1958). Other branches from the posterior spinal artery are directed medially on the surface of the cord, and from these vessels stem small penetrating arteries that supply the white matter of the posterior column on each side. Some of these vessels enter the cord directly on its posterior surface, while others enter the posterior median sulcus to penetrate the posterior columns medially.

Although there may be some anatomic continuity between a few capillaries derived from the anterior spinal artery and those derived from the posterior spinal artery, the intramedullary branches from these vessels do not form significant functional anastomoses. During life, their "functional distribution is as if they were end arteries" (Gillilan, 1958).

**RADICULAR ARTERIES.** Many authors present a confusing description of the radicular arteries because they do not differentiate between the anterior and posterior medullary feeder branches and the true dorsal and ventral radicular branches, all of which stem from the segmentally derived spinal vessels after the latter have entered the intervertebral foramina. The true radicular arteries, which nourish the nerve roots, are found at every level and on both sides of the cord (Fig. 11-38). At times some of these vessels achieve the root-cord junction and penetrate the spinal cord to assist in the supply of the most superficial parts of the gray matter in both the dorsal and ventral horns.

### **Venous Drainage of the Spinal Cord**

The veins that drain the spinal cord parenchyma are described as two principal groups: the **intramedullary veins**, which

form from the intrinsic capillaries of the spinal cord, and the intradurally located **surface veins of the spinal cord**, which receive the intramedullary veins and drain extradurally into veins in the neck, thorax, abdomen, pelvis, and spinal column, as well as the communicating venous sinuses of the cranial cavity. In general, the veins of the spinal cord follow a pattern consistent with that of the spinal arteries, but a number of differences exist. The veins of the spinal cord should not be confused with the veins of the vertebral column. These latter include the internal and external vertebral plexuses (of Batson<sup>1</sup>), which are extradural but communicate with the veins that drain the neural tissue of the spinal cord on the one hand and the systemic veins of the thorax, abdomen, and pelvis, as well as the dural sinuses of the skull on the other.

#### INTRAMEDULLARY VEINS OF THE SPINAL CORD

Venous blood from the spinal cord drains from within the neural tissue to the more superficial channels located on the surface

of the cord by means of an anterior median group of **sulcal (or central) veins**, which opens into the longitudinally coursing anterior median vein, and by a **radial group of veins**, which arises from the periphery of the gray matter or from the white matter and courses radially toward the superficial coronal plexus of veins in the pia mater (Fig. 11-40) (Gillilan, 1970).

**SULCAL (OR CENTRAL) VEINS.** Each sulcal (or central) vein is formed by the confluence of several venules just deep to the anterior median sulcus (fissure) within the substance of the anterior white commissure (Figs. 11-40; 11-41). Their location corresponds to the sulcal arteries, but contrary to the unilaterally directed arteries, the sulcal veins receive blood from both halves of the cord and even anastomose above and below with venules that form adjacent sulcal veins. The sulcal veins are less numerous and smaller than the sulcal arteries, and they open into the anterior median spinal vein, which is

<sup>1</sup>Oscar V. Batson (1894–1979): An American anatomist at the University of Pennsylvania (Philadelphia).

**Fig. 11-40.** This figure shows the sulcal (central) and radial veins within the spinal cord and their relationship to the pial and epidural venous plexuses. Convergence of the intramedullary, radicular, and epidural veins at the intervertebral foramen is shown on the right. (L. A. Gillilan, 1970).

**FIG. 11-41.** Cross section of the spinal cord and vertebral canal showing the spinal veins and the epidurally located internal vertebral plexuses of veins. (After Netter.)

located in the anterior median fissure, slightly dorsal to and to one side of the anterior spinal artery. Within the fissure there are also frequent venous anastomoses. The

sulcal veins drain the anterior gray and white commissures, the medial cell columns of the ventral horns, and the white matter of the anterior funiculi (Fig. 11-42) (Gillilan, 1970).

#### **RADIAL GROUP OF INTRAMEDULLARY VEINS.**

Arising from capillaries near the peripheral aspect of the gray matter or from the white matter are many radially oriented intramedullary veins that are directed outward toward the surface of the spinal cord, where they join the coronal venous plexus of the pia mater (Figs. 11-40; 11-41). These radial veins are more numerous in the white matter of the posterior and lateral funiculi, but they are also found in the anterior funiculi. At certain cervical and thoracic levels, the radial veins are more prominent and drain laterally from the gray matter of the lateral horn, as well as posteriorly from the dorsal nucleus of Clarke.<sup>1</sup> Other radial veins course toward the dorsal surface at or near the midline within the posterior median sulcus.

**FIG. 11-42.** Diagrammatic representation of a cross section of the spinal cord showing its venous drainage pattern. The posterior half of the cord (stippled) is drained by way of radial veins into the coronal plexus on the cord surface and then into the posterior medullary veins. The anterolateral quadrant on each side (cross hatching) is drained by radial veins into the anterior medullary veins, while the anteromedial quadrant drains into the sulcal (central) veins, which are tributaries of the anterior median vein. (L. A. Gillilan, 1970.)

<sup>1</sup>Jacob A. L. Clarke (1817-1880): An English anatomist (London).

### SURFACE VEINS OF THE SPINAL CORD

The superficial venous pattern of the spinal cord is somewhat more complex than the arterial pattern, and of the longitudinal trunks, only the **anterior median spinal vein** is consistently observed as a continuous vessel, coursing the entire length of the cord (Fig. 11-43). Frequently, **anterolateral veins** can be seen coursing longitudinally just posterior to the line of emergence of the ventral roots. On the posterior surface of the cord, the **posterior median and posterior intermediate veins** generally do not form continuous vessels (Fig. 11-43). When identifiable as longitudinal trunks, however, these are located near the posterior median and posterolateral sulci. The venous plexus on the cord surface is called the coronal plexus, while **anterior and posterior medullary veins**, which are comparable to the medullary feeder arteries, as well as the true **radicular veins**, follow the course of the nerve roots. Additionally, the **great anterior medullary vein** can usually be seen draining the lumbar enlargement.

**ANTERIOR MEDIAN SPINAL VEIN.** The anterior median spinal vein is usually found as a single longitudinally oriented trunk, located slightly dorsal to and to one side of the anterior spinal artery in the region of the anterior median fissure (Fig. 11-43). At times it may be duplicated, especially in the cervical and thoracic regions. Like its corresponding artery, the anterior median spinal vein does not have a uniform size, and it varies from 0.2 mm to as much as 0.9 mm in diameter throughout its course. Rostrally, this vein is continuous with the venous plexus located on the anterior aspect of the medulla oblongata, while caudally it tapers to form a delicate vessel along the conus medullaris. In addition to receiving the sulcal veins, the anterior spinal vein receives small pial vessels from the anterior and lateral aspects of the cord surface that help to form the coronal plexus. The anterior spinal vein is drained laterally on either side at certain segmental levels by a group of medullary veins that course toward the intervertebral foramina with the ventral roots in a manner similar to that of the anterior medullary feeder arteries.

**ANTEROLATERAL SPINAL VEINS.** When present, the anterolateral spinal veins are longitudinally oriented vessels, located in line with but slightly posterior to the ventral

roots. These veins are best developed along the cervical segments, and they receive surface vessels from the anterior and lateral aspect of the cord that help to form the coronal plexus, as well as radial veins that drain the ventrolateral parenchyma of the spinal cord (Lazorthes, Gouazé, and Djindjian, 1973).

**POSTERIOR MEDIAN SPINAL VEIN.** The posterior median spinal vein is usually an incompletely continuous longitudinal vessel located within or near the posterior median sulcus (Fig. 11-43). Its diameter is more uniform and sometimes larger than that of the anterior median spinal vein, and it receives surface collateral vessels from the coronal venous plexus. It is best developed in the cervical region of the cord but becomes more delicate and thinner along the thoracic segments. Throughout its course the posterior spinal vein receives radial veins that drain the dorsomedial part of the cord. Rostrally, the vein partially drains into the laterally directed posterior medullary vessels of the upper cervical segments and partially into the plexus of veins on the surface of the lower medulla oblongata. Caudally it extends to the conus medullaris.

**POSTERIOR INTERMEDIATE SPINAL VEINS.** Longitudinally oriented posterior intermediate spinal veins are sometimes observed overlying the posterolateral sulci in a line along the sites of entrance of the dorsal roots. These vessels frequently course for only several segments, join the surface venous plexus, and then may become longitudinally oriented once again. They usually receive radial veins that drain the dorsolateral part of the spinal cord parenchyma.

**ANTERIOR AND POSTERIOR MEDULLARY VEINS.** The superficial surface veins of the spinal cord are drained laterally at certain segmental levels by anterior and posterior medullary veins that course with some of the dorsal and ventral roots but do not drain the roots (Fig. 11-40). These veins are comparable to the medullary feeder arteries and should not be confused with the radicular veins, even though some authors do not differentiate between the medullary veins, which drain the cord, and the radicular veins, which drain the roots. The anterior and posterior medullary veins are largest and most constant at the cervical and lumbar enlargements.

There are 8 to 14 **anterior medullary veins**,

**FIG. 11-43.** The anterior (left and middle) and posterior (right) longitudinal surface veins of the human spinal cord. Note that anterior and posterior medullary veins, comparable to the medullary feeder arteries, are found at various segmental levels coursing as tributaries along certain roots from the longitudinally oriented veins. (From G. F. Domisse, *The Arteries and Veins of the Human Spinal Cord from Birth*, Churchill-Livingstone, Edinburgh, 1975.)

which stem from either the anterior median spinal vein or from the coronal plexus of veins on the anterior and anterolateral cord surface. These vessels are visible without magnification and frequently arise at segmental levels that do not have medullary feeder arteries. The **posterior medullary veins** are generally more numerous than the

anterior medullary veins, especially in the cervical region (Gillilan, 1970).

The **great anterior medullary vein** usually arises on the anterior cord surface in the lower thoracic or upper lumbar segments. This vessel descends in the cauda equina to its corresponding intervertebral foramen, along one of the anterior roots. A compara-

ble **great posterior medullary vein** is sometimes observed arising on the posterior surface of the conus medullaris. It descends along one of the posterior roots of the cauda equina to its appropriate intervertebral foramen.

**RADICULAR VEINS.** Delicate anterior and posterior radicular veins, which actually drain the anterior and posterior roots, can be found on both sides of virtually every spinal segment. They course toward the intervertebral foramina, along with the fascicles of nerve fibers forming the roots. The radicular veins are usually microscopic in size; they generally arise from the gray matter of the dorsal and ventral horns and emerge at the spinal cord-root junction. The radicular veins sometimes terminate in the venous plexus on the cord surface, but more often they terminate in the venous plexuses within the intervertebral foramina.

### MEDULLA OBLONGATA

Interconnecting the spinal cord with the cerebellum, diencephalon, and cerebral cortex is the **brain stem**, which consists of the medulla oblongata, pons, and mesencephalon (Figs. 11-44 to 11-46; 11-53; 11-54). The direct upward continuation of the spinal cord through the foramen magnum is the **medulla oblongata**, which is itself continuous rostrally with the pons. Within the human skull, the brain stem is positioned nearly vertically, and it extends from the upper border of the atlas to a plane that interconnects the jugular tubercles of the occipital bone. These limits are somewhat arbitrary, however, because there is a gradual transition in the internal anatomy of the spinal cord to that of the medulla oblongata at the upper border of the first cervical nerve. The rearrangement of gray matter and fiber tracts more rostrally within the medulla, or **bulb** as it is commonly known, is such that at the level of the decussation of the pyramids, or slightly higher at the level of the olive, a transverse section of the brain stem is totally different from one through the spinal cord.

#### *External Anatomy of the Medulla Oblongata*

The shape of the medulla oblongata is comparable to that of a truncated cone, with its smaller end directed inferiorly toward the spinal cord and its broader extremity directed superiorly toward the pons. Its ap-

proximate measurements are 3 cm longitudinally, 2 cm transversely, and 1.25 cm anteroposteriorly. The central canal continues upward from the spinal cord through its lower half, but in its upper half the medulla splits open at the dorsal median sulcus, expanding the canal into the **fourth ventricle**. The medulla oblongata may therefore be divided into a lower *closed part* containing the central canal, and an upper *open part* corresponding with the lower portion of the fourth ventricle.

### FISSURES AND SULCI

Similar to the spinal cord, the external surface of the medulla oblongata is marked by several longitudinally oriented sulci and the anterior median fissure (Figs. 11-44; 11-54).

**ANTERIOR MEDIAN FISSURE.** The anterior median fissure continues rostrally from the spinal cord in the ventral midline along the entire length of the medulla oblongata (Fig. 11-45). The fissure reaches the lower border of the pons, where it terminates in a small pit called the **foramen caecum**. In the lower medulla just above the spinal cord, the anterior median fissure becomes indistinct because it is crossed by a series of obliquely oriented nerve fiber bundles that form the **decussation of the pyramids** (Figs. 11-45; 11-47). These fibers constitute the **lateral corticospinal tracts**, which descend from the medulla oblongata to the spinal cord and cross to the opposite side. Somewhat above this decussation, delicate **anterior external arcuate fibers** emerge from the anterior median fissure and curve laterally and upward over the surface of the medulla to join the inferior cerebellar peduncle (Fig. 11-47).

**POSTERIOR MEDIAN SULCUS.** The posterior median sulcus of the medulla oblongata is a narrow groove in the dorsal midline that represents the continuation rostrally of the posterior median sulcus of the spinal cord (Figs. 11-44; 11-54). It exists only in the more caudal, closed portion of the medulla, becoming more shallow as it ascends. Finally, the posterior median sulcus ends at about the middle of the medulla, where the central canal expands into the cavity of the fourth ventricle.

**ANTERIOR LATERAL AND POSTERIOR LATERAL SULCI.** In the medulla oblongata, these sulci are the rostral continuation of the anterolateral and posterolateral sulci of the spinal

**Fig. 11-44.** The dorsal aspect of the upper spinal cord and brain stem, showing the lower eight cranial nerves and the upper cervical nerves.

cord, where they mark the lines of emergence of the ventral rootlets and the entrance of the dorsal rootlets of the spinal nerves (Fig. 11-54). In the medulla, the rootlets of the hypoglossal nerve are located in linear series with the ventral roots of the spinal cord, and they emerge from the brain stem along the anterior lateral sulcus (Fig. 11-45). Similarly, the attachments of the accessory vagus and glossopharyngeal nerves to the medulla oblongata are positioned in the depths of the posterior lateral sulcus in a line corresponding with the entrance of the dorsal roots in the spinal cord.

Because the anterior median fissure and posterior median sulcus, which are located in the midline, and the anterior lateral and posterior lateral sulci on each side are longitudinally oriented, the external surface of the medulla oblongata is divided into right and left anterior, lateral, and posterior re-

gions. These roughly correspond to the anterior, lateral, and posterior funiculi of the spinal cord. Although these three regions appear to be directly continuous with the corresponding funiculi of the spinal cord, they do not necessarily contain the same nerve fibers, because some of the tracts from the spinal cord end in the medulla while others alter their course as they pass through it.

#### ANTERIOR REGION OF THE MEDULLA

The anterior region of the medulla on each side is named the **pyramid**; it lies between the anterior median fissure and the anterior lateral sulcus (Fig. 11-45). Its upper end is slightly constricted and, at the pontomedullary junction between the pyramid and the pons, the fibers of the abducens nerve emerge from the brain stem. Slightly below the pons, the pyramid becomes enlarged and

**FIG. 11-45.** The anterior aspect of the brain stem.

prominent, whereas in the lower medulla it tapers into the anterior funiculus of the spinal cord, with which it falsely appears to be directly continuous (Fig. 11-45).

The two pyramids contain the descending motor fibers that course from the cerebral cortex to the spinal cord; these are the important **corticospinal** (or pyramidal) fibers (Figs. 11-47 to 11-50). When the corticospinal fibers are traced downward, it is found that

nearly 90% leave the pyramids in large, obliquely interdigitating bundles and cross to the other side in the anterior median fissure, where they form the **decussation of the pyramids**. This decussation almost obscures the anterior median fissure. The **crossed pyramidal** fibers descend in the posterior part of the lateral funiculus of the spinal cord as the **lateral corticospinal tract**. Some of the fibers in the lateral part of each pyramid that do not

cross in the pyramidal decussation descend in the lateral funiculus of the spinal cord as uncrossed fibers in the lateral corticospinal tract, while the remaining descend in the anterior funiculus of the spinal cord as the uncrossed **anterior corticospinal tract**. The pyramidal fibers that supply the cervical enlargement of the spinal cord and, thus, are functionally related to the musculature of the upper extremity, cross in the more rostral part of the pyramidal decussation. Those that descend to lumbosacral levels of the spinal cord, thereby supplying spinal cord levels that innervate musculature in the lower limbs, cross more caudally in the decussation.

#### LATERAL REGION OF THE MEDULLA

The lateral region of the medulla oblongata is bounded in front, or *anteriorly*, by the anterior lateral sulcus, within which emerge the roots of the **hypoglossal nerve**, and behind, or *posteriorly*, by the posterior lateral sulcus, which contains the roots of the **accessory, vagus, and glossopharyngeal nerves** (Fig. 11-45). Its upper part consists of a prominent oval mass that is named the **olive**, while its lower part is the same width as the lateral funiculus of the spinal cord and appears on the surface to be a direct continuation of it (Fig. 11-45). Actually, only a portion of the lateral funiculus of the spinal cord is continued upward into the lateral region of the medulla, because the lateral corticospinal tract is formed from the pyramidal fibers of the opposite side and most of the fibers in the **posterior spinocerebellar tract** course into the inferior cerebellar peduncle in the posterior region of the medulla oblongata. The **anterior spinocerebellar tract** continues superiorly on the lateral surface of the medulla oblongata in the same relative position that it occupies in the spinal cord (Fig. 11-47), until it passes under cover of the external arcuate fibers just dorsal to the olive and ventral to the roots of the vagus and glossopharyngeal nerves. This tract then continues upward through the pons and winds around the dorsolateral edge of the lateral lemniscus; it enters the cerebellum by traveling along the dorsal surface of the superior cerebellar peduncle (Figs. 11-48; 11-49). The remainder of the lateral funiculus of the spinal cord consists of the **lateral fasciculus proprius**, which in the medulla dips deep to

the olive and disappears from the surface, except for a small strand that remains superficial to the olive. In a depression at the upper end of this strand is found the vestibulocochlear nerve.

**THE OLIVE.** The olive is a prominent oval mass, measuring about 1.25 cm long, that is situated lateral to the pyramid, from which it is separated by the anterior lateral sulcus of the medulla oblongata and the rootlets of the hypoglossal nerve (Figs. 11-45; 11-48; 11-49). Posteriorly, its boundary is formed by the posterior lateral sulcus and the attachments of the glossopharyngeal, vagus, and accessory nerves. In a depression between the upper end of the olive and the pons are the roots of the vestibulocochlear and facial nerves. The anterior external arcuate fibers are conspicuous on the surface of the medulla as they wind across the lower part of the pyramid and olive to enter the inferior cerebellar peduncle. In cross section, the neural mass that forms the olive consists of a large, irregularly convoluted accumulation of gray matter, which includes the principal **inferior olivary nucleus** and both the **medial and dorsal accessory olivary nuclei** (Figs. 11-48; 11-49). On the surface of the olive are delicate bundles of nerve fibers, the anterior external arcuate fibers, which leave the anterior median fissure, wind across the lower part of the pyramid and olive, and enter the inferior cerebellar peduncle.

#### POSTERIOR REGION OF THE MEDULLA

The posterior region of the medulla lies behind the posterior lateral sulcus and the roots of the accessory, vagus, and glossopharyngeal nerves; like the lateral region, it is divisible into caudal and rostral parts.

The *caudal part* of the posterior region of the medulla is bounded behind by the posterior median sulcus and is the direct continuation of the posterior funiculus of the spinal cord; it consists of the **fasciculus gracilis** and the **fasciculus cuneatus** (Fig. 11-47). The fasciculus gracilis is located parallel and adjacent to the posterior median sulcus, and it is separated from the fasciculus cuneatus by the posterior intermediate sulcus and septum, which extend into the medulla from the upper cervical cord. The fasciculi gracilis and cuneatus are at first oriented vertically, but at the caudal extent of the **rhomboid fossa** they diverge from the midline in a V-

**Fig. 11-46.** The dorsal aspect of the brain stem, showing the floor of the fourth ventricle or rhomboid fossa after the structures of the roof have been cut or pulled aside.

shaped manner, and each presents an elongated enlargement. The swelling on the fasciculus gracilis is called the **tuberculum of the nucleus gracilis**; it is produced by the gray matter of the subjacent **nucleus gracilis** (Figs. 11-46; 11-54). The enlargement on the fasciculus cuneatus is called the **tuberculum of the nucleus cuneatus**, which is likewise formed by a mass of underlying gray matter, the **nucleus cuneatus** (Fig. 11-54). The nerve fibers of these two ascending spinal fasciculi terminate on the cells of these two nuclei in a pattern that suggests a somatotopic projection. A third elevation, called the **tuberculum cinereum**, is produced by the rostral continuation of the **substantia gelatinosa**, and is present in the lower part of the posterior region of the medulla. It is narrow below and gradually expands above to end 1.25 cm below the pontomedullary junction, and it is formed by an accumulation of gray matter called the **nucleus of the spinal tract of the trigeminal nerve**. Lying on the lateral aspect of the fasciculus cuneatus, it is separated from the surface of the medulla oblongata by a band of nerve fibers that forms the spinal tract of the trigeminal nerve.

The rostral part of the posterior region of the medulla oblongata is occupied on each side by the **inferior cerebellar peduncle** (sometimes called the **restiform body**), a thick, curved bundle situated between the lower part of the fourth ventricle and the roots of the glossopharyngeal and vagus nerves (Figs. 11-49; 11-50; 11-53). As they ascend, the inferior cerebellar peduncles diverge from each other and help to form the lateral boundaries of the fourth ventricle. More rostrally they become directed posteromedially, each passing to its corresponding cerebellar hemisphere. Near their entrance into the cerebellum, the inferior cerebellar peduncles are crossed by several strands of fibers, called the **striae medullares of the fourth ventricle**, which course to the median sulcus of the rhomboid fossa (Figs. 11-46; 11-54).

A demonstration of the changes that occur in the morphology of the neuraxis through the transition from the cervical spinal cord to the medulla oblongata is most commonly presented in cross sections of the brain stem at various bulbar levels. Three such cross sections of the medulla are presented in Fig-

ures 11-47 to 11-49. These show the lower medulla at the level of the decussation of the pyramids (Fig. 11-47), the midbulbar region across the middle of the olive (Fig. 11-48), and the upper medulla near the pontomedullary junction at the level of the entrance of the vestibulocochlear nerve (Fig. 11-49).

## THE PONS

The pons is continuous above with the midbrain, being bounded anteriorly and laterally from the cerebral peduncles of the midbrain by a pronounced sulcus, sometimes called the **superior pontine sulcus**. Inferiorly, the pons is continuous with the medulla oblongata at the pontomedullary junction, where anteriorly and laterally another transverse furrow, frequently called the **inferior pontine sulcus**, marks the brain stem and contains the attachments of the abducens, facial, and vestibulocochlear cranial nerves (Figs. 11-44; 11-45; 11-54).

### DORSAL SURFACE OF THE PONS

The **dorsal** or **posterior surface** of the pons has a triangular shape and forms the upper part of the floor of the rhomboid fossa. The overlying **cerebellum**, which covers much of the posterior surface of the brain stem, is separated from the dorsal pons by the fourth ventricle, the thin pontine roof of which is formed by a delicate and thin sheet of white matter called the **superior medullary velum** (Figs. 11-46; 11-51 to 11-54). The narrow central canal of the midbrain, called the **cerebral aqueduct**, opens inferiorly into the cavity of the fourth ventricle at the upper border of the dorsal pons.

### VENTRAL SURFACE OF THE PONS

The **ventral** or **anterior surface** of the pons lies against the basilar part of the occipital bone as far caudally as its jugular tubercles; rostrally, the pons extends along the clivus, beyond the sphenoccipital synchondrosis almost to the dorsum sellae on the body of the sphenoid bone. The ventral pons is cushioned from the bony skull by a sizable space called the **cisterna pontis**, which contains subarachnoid fluid (Fig. 11-52). Anteriorly, the pons forms a prominent bulge in the

brain stem that is markedly convex from side to side, but is less so from above downward (Fig. 11-45). It consists of transversely coursing pontocerebellar fibers that arch across the midline and gather on each side into a compact mass that forms the **middle cerebellar peduncle**. Superficially, these fibers give the ventral pons a transversely striated appearance.

Coursing longitudinally along the midline of the anterior pons is a shallow groove called the **basilar sulcus** (Fig. 11-45). The **basilar artery**, which lies within the cisterna pontis, frequently occupies this sulcus, but at times this vessel may curve somewhat and course to one or the other side of the groove. Several **pontine branches** (on each side) arise from the basilar artery as it ascends ventral to the pons. These course laterally, adhering closely to the surface of the ventral pons and then penetrating the surface to supply the pons with arterial blood. At times, the **labyrinthine artery** also arises from the basilar artery, ventral to the lower pons, although frequently these vessels branch from the anterior inferior cerebellar artery. The labyrinthine arteries also pass laterally, and near the pontomedullary junction, they join the facial and vestibulocochlear nerves to enter the internal acoustic meatus, eventually to supply the inner ear. The basilar sulcus is bounded on either side by an eminence caused by the descent of the corticospinal fibers through the substance of the pons.

The only cranial nerve that is attached to the pons is the fifth or **trigeminal nerve** (Fig. 11-51), although the **abducens**, **facial**, and **vestibulocochlear nerves** attach at the pontomedullary junction below, and the **trochlear nerve** emerges from the brain stem opposite the inferior colliculus just above the pons in the lower midbrain. The trigeminal nerve attaches on the upper lateral aspect of the ventral pons on each side just beyond the eminences formed by the corticospinal tracts. Each trigeminal nerve consists of a smaller, more medially and superiorly located **motor root**, and a much larger, more laterally and inferiorly placed **sensory root**. Together the two roots of the trigeminal nerve form the largest of all the cranial nerves. Vertical lines drawn immediately beyond the trigeminal nerves may be taken as the boundaries between the ventral surface of the pons and the middle cerebellar peduncle, and frequently the point of attach-

**FIG. 11-47.** Transverse section of medulla oblongata at the decussation of the pyramids. Nuclear groups represented diagrammatically in color. (From Villiger-Addison, courtesy of J. B. Lippincott Co.)

ment of the trigeminal nerve to the pons is described as the site at which the middle cerebellar peduncle arises from the pons.

#### STRUCTURE OF THE PONS

Transverse sections through the pons show that it is composed of two parts that differ in appearance and structure (Figs. 11-

50; 11-51). These are the **basilar** or **ventral part of the pons** and the dorsally located **pontine tegmentum**. The *basilar part* consists largely of fibers arranged in transverse and longitudinal bundles, together with small groups of nerve cells that constitute the **nuclei pontis** scattered between the transverse fibers. The descending bundles of longitudinally coursing corticospinal fibers

**FIG. 11-48.** Transverse section of medulla oblongata at the middle of the olive. Nuclear groups represented diagrammatically in color. (From Villiger-Addison, courtesy of J. B. Lippincott Co.)

**FIG. 11-49.** Transverse section through medulla oblongata and cerebellar peduncles at the level of the eighth cranial nerve. Nuclear groups represented diagrammatically in color. (From Villiger-Addison, courtesy of J. B. Lippincott Co.)

are more interspersed by the transverse fascicles of pontine fibers in the upper pons, whereas they aggregate conspicuously in the lower pons and move gradually nearer the ventral surface to form the anteriorly located pyramids of the rostral medulla. Contrastingly, the pontine tegmentum is a direct continuation of the medulla oblongata, and its structure reflects this fact. It consists principally of the upward extension of the retic-

ular formation and gray substance of the medulla and of important nuclear groups related to the cranial nerves and cerebellum.

#### Fourth Ventricle

The fourth ventricle is the flattened, diamond-shaped cavity of the hindbrain and it contains the cerebrospinal fluid. It is situated ventral to the cerebellum and dorsal to

**FIG. 11-50.** Transverse section through pons and cerebellum at the level of the facial nerve. Nuclear groups represented diagrammatically in color. (From Villiger-Addison, courtesy of J. B. Lippincott Co.)

**Fig. 11-51.** Transverse section through rostral part of pons. Nuclear groups represented diagrammatically in color. (From Villiger-Addison, courtesy of J. B. Lippincott Co.)

the pons and upper half of the medulla oblongata, and it is lined by a continuous sheet of epithelial cells called the **ependyma** (Fig. 11-52). Superiorly, the fourth ventricle extends the upper border of the pons, where it forms an angle of less than  $90^\circ$  (Fig. 11-54). Here its cavity is continuous with the cerebral aqueduct of the mesencephalon, through which communication is made with the cavity of the third ventricle. Inferiorly, the limit of the fourth ventricle is level with the lower end of the olive, where it forms an angle of nearly  $90^\circ$ . Its cavity opens below into the central canal of the medulla oblongata, which more inferiorly is continuous with that of the spinal cord (Fig. 11-54). Midway along the longitudinal axis of the fourth ventricle, on a level with the **striae medullares**, the ventricular cavity is prolonged outward in the form of two narrow **lateral recesses**. These are situated on each side between the inferior cerebellar peduncle and the flocculus of the cerebellum, and they extend laterally as far as the attachments of the glossopharyngeal and vagus nerves.

**LATERAL BOUNDARIES OF THE FOURTH VENTRICLE.** The lower part of each lateral boundary of the fourth ventricle is formed by the

tubercula of the cuneate and gracile nuclei, the fasciculus cuneatus, and the inferior cerebellar peduncle. The upper part of each lateral boundary consists of the middle and superior cerebellar peduncles (Fig. 11-54).

**ROOF OF THE FOURTH VENTRICLE.** The superior portion of the roof of the fourth ventricle on each side is formed by the superior cerebellar peduncle and the superior medullary velum.

The superior cerebellar peduncles, as they emerge from the central white substance of the cerebellum, pass cranially and anteriorly and form, initially, the lateral boundaries of the upper portion of the fourth ventricle (Figs. 11-53; 11-54). As they approach the inferior colliculi, the two superior cerebellar peduncles converge and form part of the superior roof of the cavity of the fourth ventricle by means of their overlapping medial portions.

The **superior medullary velum** is a thin, transparent lamina of white substance that stretches between the two superior cerebellar peduncles (Figs. 11-53; 11-54). On the dorsal surface of its lower half are prolonged the folia of the lingula of the cerebellum, where the superior medullary velum is con-

**FIG. 11-52.** Diagram showing a midsagittal view of the brain stem, cerebellum, and fourth ventricle. Note that the white arrow is located in the median aperture of the fourth ventricle (foramen of Magendie). Red, pia mater and vessels in the choroid plexus; yellow, ependymal lining; black, cerebrospinal fluid; blue, dura mater.

tinuous with the cerebellar white substance. A slightly elevated ridge, the **frenulum of the superior medullary velum**, descends upon the upper part of the superior medullary velum from between the inferior colliculi, and the trochlear nerve emerges adjacent to the sides of this frenulum.

The inferior portion of the roof of the fourth ventricle is formed primarily by the inferior medullary velum, tela choroidea of the fourth ventricle and choroid plexus, the taenia of the fourth ventricle, and the obex (Figs. 11-52; 11-53).

The **inferior medullary velum** is a thin sheet of white matter located on each side of the cerebellar nodule and consists of a layer of white matter lined on its inner (ventricular) surface by ependymal cells and on its external surface by the pia mater. It extends from the undersurface of the cerebellum, near the line of origin of the superior medullary velum, where its white matter is continuous with the peduncle of the flocculus, to its attachment on the medulla oblongata along the taenia of the fourth ventricle to the obex (Fig. 11-53). Each lateral angle of the diamond-shaped cavity of the fourth ventricle is prolonged into the lateral recess, which lies over the striae medullares and under the choroid plexus.

**Openings in the Roof of the Fourth Ventricle.** In the inferior part of the roof of the fourth ventricle are three openings or foram-

ina: the median aperture and two lateral apertures (Figs. 11-52; 11-53). Through these openings, spinal fluid produced by the choroid plexuses in the ventricular cavity can escape into the subarachnoid space.

The **median aperture** (or foramen of Magendie<sup>1</sup>) is a midline slit of variable size situated immediately above the obex at the inferior angle of the fourth ventricle (Fig. 11-53). It is approximately 2 cm long and usually a small extension of choroid plexus penetrates the aperture. This opening empties into the cerebellomedullary cistern. The **lateral apertures** (or foramina of Luschka<sup>2</sup>) are found at the extremities of the lateral recesses, just caudal to the point at which the middle cerebellar peduncle on each side courses into the cerebellum (Fig. 11-53). Located between the flocculus of the cerebellum and the vagus nerve on each side, the lateral apertures of the fourth ventricle are frequently occupied by small projections of choroid plexus that protrude into the subarachnoid space.

**CHOROID PLEXUSES.** The choroid plexuses of the fourth ventricle are formed by two highly vascular, elongated tufts of capillary size that are extensions of the tela choroidea and are covered by a secretory epithelium.

<sup>1</sup>François Magendie (1783-1855): A French experimental physiologist and pathologist (Paris).

<sup>2</sup>Hubert Luschka (1820-1875): A German anatomist (Tübingen).

**Fig. 11-53.** The dorsal surface of the inferior medullary velum and the foramina of the fourth ventricle as seen after removal of the cerebellum. (From F. A. Mettler, *Neuroanatomy*, C. V. Mosby, St. Louis, 1942.)

These become invaginated into the cavity of the fourth ventricle, protruding inward from the roof, and each consists of a vertical and a horizontal portion. The two vertical portions lie close to the midline on each side, whereas the horizontal portions pass laterally at right angles to the vertical portions, coursing toward the lateral recesses and even projecting beyond their apices through the lateral apertures. Thus, the right and left horizontal halves are joined in the midline and the entire structure presents the form of the letter T, the vertical limb of which, however, is doubled.

**FLOOR OF THE FOURTH VENTRICLE OR RHOMBOID FOSSA.** The anterior wall of the fourth ventricle constitutes the floor of that cavity; it has a rhomboid shape and, therefore, is called the **rhomboid fossa** (Figs. 11-44; 11-46; 11-54). Formed by the dorsal surface of the pons and the more rostral open half of the

medulla oblongata, it is covered by a thin layer of gray substance that is directly continuous with that which surrounds the central canal of the medulla oblongata below and the cerebral aqueduct above. Superficial to this is a thin layer of neuroglia, the surface of which is lined by ependymal cells.

The rhomboid fossa consists of three parts: superior, intermediate, and inferior. The **superior part** has a triangular shape, and it is limited laterally by the superior cerebellar peduncles (Fig. 11-54). The apex of this triangular region is directed cranially and is continuous with the tissue forming the wall of the cerebral aqueduct. The base is represented by an imaginary line across the brain stem at the level of the upper end of two small depressions called the **superior foveae**. The **intermediate part** extends caudally from this level to another imaginary line at the level of the horizontal portions of the

**Fig. 11-54.** The dorsal aspect of the brain stem following the removal of the cerebellum to expose the floor of the fourth ventricle. (Redrawn and slightly modified from F. A. Mettler, *Neuroanatomy*, C. V. Mosby, St. Louis, 1942.)

taenia of the fourth ventricle (Fig. 11-46). This part narrows somewhat above, where it is limited laterally on each side by the middle cerebellar peduncles, but it widens caudally where it is prolonged into the lateral recess of the fourth ventricle. The **inferior part** is triangular and its apex, which is directed caudally, is continuous with the wall of the central canal of the closed part of the medulla oblongata (Figs. 11-46; 11-54). The apex of this inferior part, which bears some resemblance to the point of a quill pen, is called the **calamus scriptorius**.

The symmetrical right and left halves of

the rhomboid fossa are divided in the midline by a **median sulcus** (Fig. 11-54). This longitudinal furrow reaches from the upper apex to the lower apex of the fossa, but it is deeper caudally than above. On each side of the median sulcus is an elevation, the **medial eminence**, which is itself bounded laterally by another sulcus called the **sulcus limitans** (Fig. 11-54). In the more rostral part of the rhomboid fossa, each medial eminence has a width equal to that of the entire corresponding half of the fossa, but opposite the superior fovea it forms an elongated swelling called the **facial colliculus**. This latter struc-

ture overlies the nucleus of the abducens nerve and is formed, at least in part, by the ascending portion of the root of the facial nerve. In the inferior part of the floor of the fourth ventricle, the medial eminence forms a triangular area called the **trigone of the hypoglossal nerve**. Careful examination reveals that this trigone consists of medial and lateral zones separated by a series of oblique furrows. The medial zone corresponds to the rostral part of the **nucleus of the hypoglossal nerve**, while the lateral zone corresponds to the **nucleus intercalatus** (Figs. 11-48; 11-54).

As just described, the **sulcus limitans** forms the lateral boundary of the medial eminence. In the superior part of the rhomboid fossa, it corresponds with the lateral limit of the fossa and has a bluish-gray zone named the **locus ceruleus** (Fig. 11-51). This region owes its color to an underlying patch of deeply pigmented nerve cells called the **nucleus pigmentosus pontis** or **substantia ferruginea**; many of these cells are now known to contain catecholamines, especially norepinephrine. At the level of the facial colliculus, the sulcus limitans widens into a flattened depression, the **superior fovea**, and in the inferior part of the fossa there appears in the floor of the ventricle a distinct dimple called the **inferior fovea** (Fig. 11-54). Lateral to these foveae is a rounded elevation, the **vestibular area**, which extends into the lateral recess as the **cochlear tubercle** and indicates the positions of the underlying vestibular and dorsal cochlear nuclei. Winding around the inferior cerebellar peduncle and crossing the vestibular area and medial eminence are strands of white nerve fibers, the **striae medullares** (Fig. 11-54). These course to the midline and penetrate the brain stem through the median sulcus.

Below the inferior fovea and between the trigone of the hypoglossal nerve and the lower part of the vestibular area is another triangular dark field called the **trigone of the vagus nerve** (previously called the *ala cinerea*). This indicates the position of the subjacent **dorsal (efferent) nucleus of the vagus nerve**. The lower end of the trigone of the vagus nerve is crossed by a translucent ridge, the **funiculus separans**, and between this and the tuberculum of the nucleus gracilis is a small tongue-shaped region called the **area postrema** (Fig. 11-54). The funiculus separans is formed by a strip of thickened

ependyma, while the area postrema consists of a highly vascular zone of neuroglial cell types, as well as nerve cells of moderate size.

## THE CEREBELLUM

The cerebellum is located dorsal to the pons and medulla oblongata and occupies the space between the brain stem and the occipital lobes of the cerebral cortex (Fig. 11-55). The **cerebellar hemispheres** rest on the floor of the posterior cranial fossa, and the median cerebellar region, called the **vermis**, is separated from the brain stem by the fourth ventricle. Intervening between the cerebellum and the posterior portion of the cerebral hemispheres is a dense sheet of dura mater, the **tentorium cerebelli**. The cerebellum is connected to the brain stem on each side by three peduncles: superior, middle, and inferior. The **superior cerebellar peduncle** (brachium conjunctivum) connects the cerebellum to the midbrain, while the **middle peduncle** (brachium pontis) and **inferior peduncle** (restiform body) attach the cerebellum to the pons and medulla oblongata, respectively (Figs. 11-62; 11-63).

Although the cerebellum probably does not initiate voluntary movement, it appears to serve as a suprasegmental coordinator of muscular activity, especially those motor functions that require sequential, repetitive, or complex movements. Additionally, it helps to regulate muscular tone and to maintain a proper balance for standing, walking, and running (Gilman, Bloedel, and Lectenberg, 1981). Once developed and fully matured, cerebellar connections appear to be capable of influencing the functions of virtually all parts of the central nervous system, and yet the cerebellum is not essential for life, since certain individuals "who are born without a cerebellum do not betray themselves in daily life by any defects" (Brodal, 1981). Which brain regions, through the processes of plasticity, assume the normal cerebellar functions under these circumstances is unknown. In contrast, individuals whose central nervous system has matured with a normally functioning cerebellum frequently suffer severe motor symptoms as a result of cerebellar disease.

The cerebellum is somewhat oval, is constricted in its median portion, and nearly

**FIG. 11-55.** Median sagittal section of brain. Observe that the cerebellum is interposed between the occipital lobes of the cerebral cortex and the brain stem.

flattened from above downward; its greatest diameter is from side to side. The surface of the cerebellum is not convoluted as is that of the cerebrum, but it is traversed by numerous curved furrows or fissures. The **cerebellar fissures** vary in depth in the different regions and result in the formation of the **cerebellar folia**; these present to the cerebellar surface a leaf-like, laminated appearance. The average weight of the cerebellum in the male is 150 gm. In the adult the proportion between the cerebellum and cerebrum is about 1 to 8, while in the infant it is about 1 to 20.

#### **Gross Form and Topography of the Cerebellum**

Although terms implying a functional or even phylogenetic subdivision of the cerebellum have been used, anatomically the cerebellum consists of a narrow median portion, called the **vermis**, which is located between two laterally and posteriorly protrud-

ing **cerebellar hemispheres** (Figs. 11-56 to 11-60). On the inferior surface at the rostral end of each cerebellar hemisphere is found a small, but somewhat separate, lateral projection called the **flocculus**. This attaches medially to the **nodulus** portion of the vermis by means of the **floccular peduncle** (Figs. 11-58 to 11-60,A).

#### **FISSURES OF THE CEREBELLUM**

The surface of the cerebellum is marked by a series of transversely directed fissures that are somewhat curved and extend into the cerebellar substance for a considerable distance. These divide the cerebellum into a series of lobes and lobules.

**HORIZONTAL CEREBELLAR FISSURE.** The horizontal fissure is the largest, deepest, and perhaps the most distinctive of the cerebellar fissures (Figs. 11-57 to 11-59). It commences in front of the pons near the middle cerebellar peduncles and passes horizontally and laterally on each side. It then

**FIG. 11-56.** The superior surface of the cerebellum. (Redrawn after Sobotta.)

sweeps entirely around the free margin of the cerebellar hemispheres to the posterior cerebellar notch located in the midline behind. The horizontal fissure is used as the landmark that divides the cerebellum into its **superior** and **inferior surfaces** (Figs. 11-57; 11-60, A, B). Several smaller, but nonetheless deep, fissures divide the cerebellum into lobes or lobules, and these are further subdivided by more shallow furrows into individual folia. The most clearly visible fis-

sure on the superior surface is the primary fissure (Figs. 11-56; 11-60; 11-61).

**PRIMARY FISSURE.** The primary fissure separates the anterior and posterior lobes of the cerebellum (Fig. 11-60). Those parts of the cerebellum rostral to this fissure constitute the anterior lobe and those parts behind the primary fissure, as far as the flocculonodular lobe, constitute the posterior lobe. When viewed from the superior surface, the primary fissure is V-shaped, with its apex

**FIG. 11-57.** Inferior surface of the cerebellum. (Redrawn after Sobotta.)

**FIG. 11-58.** The cerebellum viewed from its anterior or ventral aspect. (Redrawn after Sobotta.)

directed backward toward the median line and the limbs of the V directed anterolaterally as far as the horizontal fissure (Fig. 11-56).

**POSTEROLATERAL FISSURE.** The posterolateral fissure is located rostrally on the inferior surface of the cerebellum (Figs. 11-60;

11-61). It lies behind the flocculus and the floccular peduncle on each side and extends medially behind the nodulus, thereby separating the flocculonodular lobe from the remainder of the cerebellar hemispheres. It is the earliest of the cerebellar fissures to appear during embryonic development.

**FIG. 11-59.** The anteroinferior aspect of the cerebellum and pons. The right (reader's left) tonsil and a part of the biventer lobule have been removed and the pons has been sectioned transversely, exposing the flocculonodular lobe and the bed of the cerebellar tonsil. (Redrawn after Sobotta.)

**Fig. 11-60.** Diagrammatic representations of the lobes of the cerebellum (A and C) and their constituent lobules (A) and divisions of the vermis (A, B, and C). Note also the principal fissures. (From E. L. House, B. Pansky, and A. Siegel, *A Systematic Approach to Neuroscience*, McGraw-Hill, New York, 1979.)

**OTHER CEREBELLAR FISSURES.** Other frequently named cerebellar fissures visible from the superior surface include the **postlingual fissure**, located behind the lingula of the vermis; the **postcentral fissure**, lying between the alae of the central lobule and the quadrangular lobules; and the **posterior superior fissure** (also called the postclival or postlunate fissure), seen between the lobulus simplex and the superior semilunar lobule (Fig. 11-61). Visible on the inferior surface of the cerebellum are the **prepyramidal fissure**, located between the inferior semilunar lobule and the biventer lobule, as well as the **secondary fissure** (also called the retrotonsillar fissure or postpyramidal fissure), which is found between the uvula and pyramid medially and between the biventer lobule and the tonsil more laterally (Fig. 11-61).

#### VERMIS OF THE CEREBELLUM

The **vermis** of the cerebellum lies between the cerebellar hemispheres and is a continuous but unpaired narrow median region visible on both the superior and inferior cerebellar surfaces (Figs. 11-56 to 11-59; 11-60, B; 11-61). Its name is derived from the Latin word *vermis* (meaning a worm) because the surface shape of this median cerebellar region resembles a worm bent nearly completely back onto itself to form a slender circular structure. On the superior surface, the **superior vermis** forms a midline elevation that throughout its length nearly blends with the cerebellar hemispheres (Figs. 11-56; 11-61). In contrast, the **inferior vermis** is sunken and lies at the bottom of a longitudinally oriented hollow space called the **cerebellar vallecula**, located between the hemispheres (Figs. 11-57 to 11-59).

**SUPERIOR VERMIS.** The superior vermis is subdivided by short, deep, transverse fissures that form, from front to back, parts of the vermis called the **lingula**, **central lobule**, **culmen**, **declive**, and **folium vermis** (Figs. 11-56; 11-60; 11-61). Of these, only the lingula is not joined laterally to a portion of the cerebellar hemispheres; instead, the white matter of its four or five folia is continuous with the superior medullary velum (Fig. 11-61). Consisting of a small tongue-shaped process, the **lingula** lies in front of and is concealed by the central lobule. It is separated from the central lobule by the postlingual fissure. The **central lobule** is continuous laterally with

the alae of the central lobule, while the **culmen**, lying just in front of the primary fissure, is joined laterally on each side to the quadrangular lobule. The portion of the vermis directly behind the primary fissure is the **declive**, and this is laterally contiguous with the lobulus simplex on each side. The most caudal part of the vermis visible from the superior surface is the **folium vermis**, which is joined to the superior semilunar lobules laterally. The folium vermis is a short, narrow, and somewhat concealed band that seems to consist of a single folium, but in reality is marked on its upper and lower surfaces by secondary fissures. The folium vermis and the superior semilunar lobules on each side lie immediately above the horizontal fissure.

**INFERIOR VERMIS.** The inferior vermis is similarly divided into smaller segments by transversely coursing fissures. Progressing rostrally from the most caudal part, these are called the **tuber vermis**, **pyramis** (vermis), **uvula** (vermis), and **nodulus** (Figs. 11-57 to 11-61). The **tuber vermis** is small and continuous laterally with the inferior semilunar lobules. These are located just below the horizontal fissure. Rostral to the tuber vermis is the **pyramis** (vermis), which is joined on each side to the biventer lobules. In front of the pyramis is the **uvula** (vermis), bounded laterally by the nearly spherical cerebellar tonsils. The uvula forms a considerable portion of the inferior vermis. It is separated on each side from the tonsil by the **sulcus valleculae**, at the bottom of which it is connected to the tonsil by a ridge of gray matter that is indented on its surface by shallow furrows and hence called the **furrowed band**. Finally, the most rostral part of the inferior vermis is called the **nodulus**. This is attached on each side to the flocculus by the floccular peduncles. Together the nodulus, the two flocculi and their peduncles form the flocculonodular lobe, which is separated from the cerebellar tonsils and the uvula (vermis) by the posterolateral fissure.

#### CEREBELLAR HEMISPHERES

In addition to the centrally located vermis, it is customary to consider the cerebellum as composed of two large laterally projecting masses called the **cerebellar hemispheres**. As described previously, these are continuous with the vermis on both the superior and

**Fig. 11-61.** Sagittal section through the vermis of the cerebellum. (From E. C. Crosby, T. Humphrey, and E. W. Lauer, *Correlative Anatomy of the Nervous System*, Macmillan Publishing Co., New York, 1962.)

inferior cerebellar surfaces (Figs. 11-56 to 11-59). Each hemisphere is composed of eight lobules, arranged in pairs so that the total shape of the two hemispheres is nearly symmetrical. Four pairs of lobules lie above the horizontal fissure and, therefore, are visible on the superior cerebellar surface, while four pairs of lobules lie below the horizontal fissure and can only be clearly seen if the cerebellum is viewed from below or if it is detached from its brain stem connections and turned to expose the inferior cerebellar surface.

The eight cerebellar lobules that form each cerebellar hemisphere are named, from front to back on the superior surface, the **ala of the central lobule**, the **quadrangular lobule**, the **lobulus simplex**, and the **superior semilunar lobule**, and from back to front on the inferior surface, the **inferior semilunar lobule**, the **biventer lobule**, the **cerebellar**

**tonsil**, and the **flocculus** (Figs. 11-56 to 11-60,A).

The most rostral part of the cerebellar hemispheres on the anterior surface forms the *alae of the central lobule*. These thin, wing-like prolongations of the central lobule of the vermis extend laterally along the upper and anterior part of each hemisphere. Behind the alae of the central lobule and separated from them by the postcentral fissure on each side are the *quadrangular lobules* (Fig. 11-56). The surface of these lobules is roughly four-sided; medially they are continuous with the culmen, and caudally they are separated from the lobulus simplex by the primary fissure.

Behind the primary fissure are the relatively large *lobuli simplex*. These lobules are continuous medially with the declive, and their superior surfaces are also nearly four-sided, although their caudal borders are

curved. They are bounded behind by the posterior superior fissure (also called the postclival fissure or postlunate fissure). The most caudal part of the cerebellar hemispheres as seen from above is formed by the large half moon-shaped superior semilunar lobules. Expanding laterally from the small medially located folium of the vermis, they form the entire posterior one-third of the superior surface of the cerebellum. The superior semilunar lobules are bounded below by the horizontal fissure (Figs. 11-56; 11-58; 11-60,A).

The posterior two-thirds of the inferior surface of each cerebellar hemisphere consists of the *inferior semilunar lobule* (Fig. 11-57). Expanding laterally from the small, medially placed tuber vermis, these large lobules lie below the horizontal fissure and behind the prepyramidal fissure. In front of the inferior semilunar lobules are the *biventer lobules*. On their surface these are somewhat triangular, with their apices projected backward, and medially they are joined to the pyramis (vermis). The *cerebellar tonsils* are rounded masses situated medially and slightly rostral to the biventer lobules, and each lies in a deep fossa on the posterior cerebellar surface called the *nidus avis* (bird's nest) (Fig. 11-59). The cerebellar tonsils are continuous medially with the uvula. Finally, each cerebellar hemisphere has appended to it the *flocculus*. Each flocculus is a prominent, irregular lobule situated in front of the biventer lobule and behind the middle cerebellar peduncle. It is subdivided by furrows into a few small folia and it is attached medially to the nodulus. The flocculus is also con-

nected to the inferior medullary velum by its central white core (Figs. 11-58; 11-59).

### LOBES OF THE CEREBELLUM

A commonly used and sometimes convenient way to describe cerebellar development and adult cerebellar anatomy and physiology is to divide the cerebellum into the *flocculonodular lobe* and the *corpus cerebelli*. As described previously, the **flocculonodular lobe** includes the flocculi, their peduncles, and the centrally located nodulus. It is bounded behind by the posterolateral fissure, which both phylogenetically and ontogenetically is the first fissure to appear in the cerebellum. The remainder of the cerebellum is considered the *corpus cerebelli*, which consists of all of the vermis except the nodulus and all of the cerebellar hemispheres except the flocculi. *The primary fissure is the important landmark in dividing the corpus cerebelli into its anterior and posterior lobes* (Figs. 11-56; 11-60,C).

The **anterior lobe** is the part of the cerebellum that extends between the superior medullary velum and the primary fissure. It includes the lingula, central lobule and culmen of the vermis, and the alae of the central lobules, as well as the quadrangular lobules (Figs. 11-56; 11-60, C). Phylogenetically, it is the oldest part of the corpus cerebelli, but it does not appear as early as the flocculonodular lobe.

The remainder of the corpus cerebelli is considered the **posterior lobe**. It includes the declive, folium vermis, tuber vermis, pyramis (vermis), and uvula (vermis) portions of

Parts of the Human Cerebellum

Cerebellar Lobes	Cerebellar Lobule	Vermis
Anterior Lobe	—	Lingula Central lobule
	Ala of the central lobule	
	Quadrangular lobule	Culmen
Posterior Lobe	Lobulus simplex	Declive
	Superior semilunar lobule	Folium vermis
	Inferior semilunar lobule	Tuber vermis
	Biventer lobule	Pyramis (vermis)
	Cerebellar tonsil	Uvula (vermis)
Flocculonodular Lobe	Flocculus	Nodulus

the centrally located vermis, and the lobuli simplex, superior and inferior semilunar lobules, the biventer lobules, and the cerebellar tonsils (Figs. 11-57 to 11-60). The posterior lobe is much larger than the anterior lobe and most of it has a more recent phylogenetic history than does the anterior lobe.

The flocculonodular lobe, which essentially subserves the vestibular system in its function, is often called the **archeocerebellum** (Figs. 11-58; 11-59). The anterior lobe along with the pyramis (vermis) and the uvula (vermis) of the posterior lobe are generally considered to constitute the **paleocerebellum**, which receives essentially afferent projections from the spinal cord by way of the spinocerebellar septum. The remainder of the cerebellum—i.e., the posterior lobe minus the pyramis and uvula—is a relatively late phylogenetic acquisition, often called the **neocerebellum**, and it receives projections from the cerebral cortex by way of the relay nuclei in the pons. Although not strictly consistent with all experimental data, these three regions could be considered vestibulocerebellar (archeocerebellum), spinocerebellar (paleocerebellum), and pontocerebellar (neocerebellum) with respect to the origin of their afferent connections.

#### CEREBELLAR ATTACHMENTS TO THE BRAIN STEM

The cerebellum is physically connected to the brain stem by way of the superior medullary velum, the inferior medullary velum, and the inferior, middle, and superior cerebellar peduncles.

**SUPERIOR MEDULLARY VELUM.** The superior medullary velum is a single, thin, transparent lamina of white matter that stretches between the superior cerebellar peduncles (Figs. 11-58; 11-59; 11-61). It is narrow above, where it passes beneath the inferior colliculi of the midbrain and broader below, where it is continuous with the white matter of the superior vermis. Together with the superior cerebellar peduncles, it forms the upper part of the roof or posterior wall of the fourth ventricle. A slightly elevated ridge, the **frenulum of the superior medullary velum**, descends upon its upper part from between the inferior colliculi, and on either side of the frenulum, the trochlear nerves emerge from the brain stem.

**INFERIOR MEDULLARY VELA.** The inferior medullary vela are two thin layers of white

matter, one on each side, which are attached to the front and lower surface of the nodule and are then extended laterally along the peduncles of the flocculi (Figs. 11-58; 11-59; 11-61). Each inferior medullary velum has a nearly semilunar shape and its neural elements extend only as far as its crescentic lower border; beyond this, as it covers the inferior part of the fourth ventricle, the inferior medullary velum is formed essentially of a layer of ependymal epithelium supported by a backing of pial tissue, the **tela choroidea**. This attaches inferiorly to the surface of the medulla along the taenia of the fourth ventricle. It is somewhat deficient in its lower part where the median aperture of the fourth ventricle allows that cavity to communicate directly with the subarachnoid space on the surface of the brain.

**INFERIOR CEREBELLAR PEDUNCLES.** The inferior cerebellar peduncles, or *restiform bodies*, are a pair of prominent, rounded masses of nerve fibers that interconnect the rostral part of the posterior region of the medulla oblongata and the cerebellum (Figs. 11-62; 11-63). Each is situated between the floor of the fourth ventricle and the emerging roots of the glossopharyngeal and vagus nerves. Initially, the inferior cerebellar peduncles pass upward and then diverge laterally to form a part of the lateral walls of the fourth ventricle. After they ascend to the cerebellum and reach the anterior cerebellar notch, they bend abruptly backward and each passes to its corresponding cerebellar hemisphere. As it enters the cerebellum, the inferior cerebellar peduncle lies between the superior cerebellar peduncle medially and the middle cerebellar peduncle laterally. The inferior cerebellar peduncles carry both afferent and efferent fibers with respect to the cerebellum, and these interconnect the cerebellum principally to structures in the spinal cord and medulla oblongata.

**MIDDLE CEREBELLAR PEDUNCLES.** The middle cerebellar peduncles, or *brachia pontis*, are the largest of the three pairs of cerebellar peduncles. They arch upward to the cerebellum from the brain stem, where they are located in the dorsolateral, midpontine region just rostral to the penetration sites of the facial and vestibulocochlear nerves (Figs. 11-58; 11-62; 11-63). Consisting principally of afferent fiber tracts from the pontine nuclei which cross from the opposite side in the pons, the middle cerebral peduncles enter

**FIG. 11-62.** Drawings of partially dissected brain stems illustrating the relationships of the cerebellar peduncles. (A) From the anteroinferior aspect; (B) from the posterosuperior aspect. (From E. C. Crosby, T. Humphrey, and E. W. Lauer, *Correlative Anatomy of the Nervous System*, The Macmillan Publishing Co., New York, 1962.)

the rostral part of the inferior surface of the cerebellum lateral to the attachments of the superior and inferior peduncles.

The fibers that form the middle cerebellar peduncle are arranged in three fascicles:

superior, inferior, and deep. The **superior fasciculus** is formed by the more rostral transverse fibers of the pons, and it is directed backward and laterally and is more superficial to the other two fasciculi. Its cer-

**Fig. 11-63.** Dissection showing the projection fibers of the cerebellum. (After E. B. Jamieson.)

ebellar afferent fibers are distributed mainly to the lobules on the inferior surface of the cerebellar hemispheres and to the parts of the superior surface that adjoin the posterior and lateral margins. The **inferior fasciculus** is formed by the most caudal transverse fibers of the pons. It passes from the pons under cover of the superior fasciculus, and continues downward and backward, parallel to the superior fasciculus, and becomes distributed to the cerebellar folia of the inferior surface near the vermis. The **deep fasciculus** is composed principally of deep transverse fibers of the pons. Initially, it is covered by the superior and inferior fasciculi, but it then crosses obliquely to appear on the medial side of the superior fasciculus, from which it receives a bundle. Its fibers then spread out to pass to the cerebellar folia in the anterior part of the superior surface. The fibers of this fasciculus cover those of the inferior cerebellar peduncle.

**SUPERIOR CEREBELLAR PEDUNCLES.** Each of the two superior cerebellar peduncles, frequently called a *brachium conjunctivum*, emerges from the cerebellum medial to the middle peduncle and medial and superior to the inferior peduncle (Figs. 11-58; 11-59; 11-62; 11-63). It joins the cerebellum and the midbrain and contains the most important efferent fiber bundles from the cerebellum. The two superior peduncles are joined to each other across the midline by the superior medullary velum, and from the cerebel-

lum they can be followed superiorly as far as the inferior colliculi, under which they disappear. Along their ascent the superior cerebellar peduncles first form the dorsolateral boundaries of the fourth ventricle, but more superiorly they converge on the dorsal aspect of the ventricle and thus assist in forming its roof.

Most of the fibers that form the superior cerebellar peduncles arise from cells in the dentate nuclei of the cerebellum, although others come from the emboliform, globose, and fastigial nuclei. Coursing into the pontine tegmentum and lower midbrain, most of the fibers course medially and cross to the opposite side ventral to the cerebral aqueduct. They terminate in many brain stem and thalamic structures, including the red nucleus, the reticular formation of the midbrain, the pons, and the medulla oblongata, the oculomotor nucleus, and several thalamic nuclei, especially the ventrolateral nucleus. Afferent fibers in the superior cerebellar peduncles are derived from the ventral spinocerebellar tract, as well as from neurons in the colliculi of the midbrain.

## THE MIDBRAIN

The midbrain or mesencephalon is that part of the neuraxis located between the pons inferiorly and the thalamus and hypothalamus superiorly (Fig. 11-64). It is a short,

Fig. 11-64. A dorsolateral view of brain stem.

constricted segment of the brain stem, measuring only about 2 cm. Inferiorly, the boundary of the midbrain is represented by a transverse plane passing just caudal to the inferior colliculi posteriorly and just rostral to the ventral pons anteriorly, where the superior pontine sulcus marks the upper limit of the transverse pontine fibers. Superiorly, the midbrain is limited by another transverse plane that passes through the posterior commissure dorsally and just behind the mammillary bodies of the posterior hypothalamus ventrally.

By definition, each half of the midbrain is called a **cerebral peduncle**, and this is further divided into a ventral part, called the **crus cerebri**, and a dorsal part, called the **midbrain tegmentum**. In a cross section of the midbrain, it can be seen that the crus cerebri and the tegmentum are separated on both sides by a layer of pigmented nerve cells, the **substantia nigra**. A slender canal, the **cerebral aqueduct**, passes longitudinally through the midbrain and interconnects the third ventricle of the diencephalon above with the fourth ventricle below. Surrounding the cerebral aqueduct is a layer of gray matter called the **periaqueductal central gray substance**. The portion of the midbrain dorsal to the cerebral aqueduct is called the **tectum** and it consists principally of four rounded swellings or eminences—a pair of **superior colliculi** and a pair of **inferior colliculi** (Fig. 11-64). Also called the **corpora quadrigemina**, the superior and inferior

colliculi on each side of the dorsal midbrain surface are easily identifiable and made more prominent because they are separated by a shallow sulcus.

### Basal Part of the Midbrain

The basal part of the midbrain consists of the crus cerebri and the substantia nigra on each side (Figs. 11-65; 11-67; 11-68).

**CRUS CEREBRI.** Coursing along the ventrolateral aspect of the midbrain on both sides are longitudinally oriented fissures that mark the boundary between the tegmentum dorsally and the crus cerebri ventrolaterally. Each crus cerebri consists of large bundles of nerve fibers that originate in the cerebral cortex and descend as the corticobulbar and corticospinal tracts through the internal capsule and terminate either in the brain stem below the mesencephalon or in the spinal cord. The crura cerebri also contain corticopontine fibers that arise from the frontal, parietal, temporal, and occipital lobes and end in the pontine nuclei. After emerging from the cerebrum, the two crura cerebri form the most ventral part of the midbrain, and on each side they appear as broad, compact bands that are semilunar in transverse section (Fig. 11-65).

Between the crura cerebri is located the wedge-shaped **interpeduncular fossa**, the dorsal floor of which is formed of gray matter and called the **posterior perforated substance** because branches of the posterior cerebral artery pierce the midbrain at this site. During their descent through the mesencephalon, the two crura cerebri converge, and as they enter the rostral region of the ventral pons, they meet on each side of the midline, being separated only by the emerging oculomotor nerves. At this site, the medial surface of each crus is marked by a longitudinal furrow, the **medial sulcus of the crus cerebri**, along which the **oculomotor nerves** pass (Fig. 11-68).

The ventral surface of each crus is crossed from medial to lateral by the superior cerebellar and posterior cerebral branches of the basilar artery. The lateral surfaces of the crura are in relationship to the parahippocampal gyri of the cerebral hemispheres, and the **trochlear nerves**, which leave the brain stem dorsally, wind around the sides of the crura from dorsal to ventral. Also, the lateral surface of each crus is marked by a longitudinal furrow called the **lateral sulcus**

**of the mesencephalon.** The fibers of the lateral lemniscus come to the surface in this sulcus and then turn dorsally to pass to the inferior colliculus and its brachium. As the crura emerge from the cerebral hemispheres to enter the midbrain, they course deep (dorsal) to the optic tracts, which are themselves directed laterally and somewhat caudally to their connections in the lateral thalamus (Fig. 11-65).

When viewing the crescentic shape of the crura cerebri in transverse section, it is frequently stated that the middle three-fifths of each crus is occupied by corticospinal and corticonuclear (corticobulbar) fibers arranged in a somatotopic pattern. These are the great motor pathways. Beyond the midbrain, the **corticospinal fibers** descend through the pons to form the pyramids of the medulla oblongata; most (70 to 90%) then decussate to form the crossed lateral corticospinal tracts, while the remainder descend uncrossed into the cord to form the ventral corticospinal tract. The **corticonuclear fibers** descend and terminate in or near the motor nuclei of the cranial nerves. Most of these decussate but some supply certain motor nuclei ipsilaterally. Within this middle region of the crus, descending corticospinal

fibers to the lower extremity are located more laterally, while corticonuclear fibers serving the motor nuclei that control the musculature of the face, oropharynx, and larynx are located more medially. Interposed between these are the corticospinal fibers that serve the upper extremity.

Other efferent fibers from the cerebral cortex occupy the medial one-fifth and lateral one-fifth of the crura cerebri. These are the **corticopontine tracts**, which descend to synapse in the pontine nuclei, from which pontocerebellar fibers then cross transversely in the pons and project to the contralateral cerebellar hemisphere. From the frontal lobes, ipsilateral frontopontine fibers occupy the medial one-fifth of each crus cerebri, while temporopontine, parietopontine, and occipitopontine fibers originating in the temporal, parietal, and occipital lobes of the cerebral cortex are found in the lateral one-fifth of each crus.

**SUBSTANTIA NIGRA.** Located just dorsal to the crus cerebri on each side of the basal part of the midbrain is a layer of gray substance, the substantia nigra, which in transverse section also presents a semilunar shape with its concavity directed dorsally toward the tegmentum (Figs. 11-65; 11-67;

**Fig. 11-65.** Caudal view of the transversely sectioned midbrain, the ventral surface of the hypothalamus, and the optic tract. (After Sobotta.)

The tegmentum consists of bundles of longitudinally and transversely oriented fiber tracts, as well as masses of diffuse gray matter. It contains aggregations of nerve cells that are frequently assembled in cell groups and collectively are referred to as the tegmental nuclei. In the more dorsal tegmental region, ventral to the cerebral aqueduct and its surrounding gray substance, are found the nuclei of the trochlear and oculomotor nerves, while the mesencephalic nucleus of the trigeminal nerve is situated more dorso-laterally (Figs. 11-67; 11-68).

**MESENCEPHALIC NUCLEUS OF THE TRIGEMINAL NERVE.** This nucleus is formed by the cell bodies of primary sensory neurons and is located in the lateral part of the central gray substance that surrounds the aqueduct. Its unipolar, rounded neurons are arranged in small clusters that extend along the lateral angle of the fourth ventricle from the main sensory nucleus of the trigeminal nerve in the pons to the upper midbrain. The axons of its cells gather at the lateral border of the nucleus to form the tract of the mesencephalic nucleus, from which collaterals form monosynaptic connections with neurons in the trigeminal motor nucleus. These sensory nerve cells are thought to serve a proprioceptive function for the muscles of mastication, the teeth, and possibly even certain facial and extraocular muscles.

**TROCHLEAR NUCLEUS.** The trochlear nucleus is located at the level of the inferior colliculus; it consists of a compact group of cells in the ventral part of the central gray substance, close to the midline and just dorsal to the medial longitudinal fasciculus (Fig. 11-67). The trochlear fibers arch dorsally and laterally around the central gray substance, decussate in the superior medullary velum, and emerge at the dorsal surface of the brain stem just behind the inferior colliculus (Fig. 11-66).

**OCULOMOTOR NUCLEUS.** The oculomotor nucleus is a complex of nuclear groups found just ventral to the cerebral aqueduct and its surrounding central gray substance in a wedge-shaped region bounded by the medial longitudinal fasciculi of the two sides, immediately rostral to the trochlear nucleus (Figs. 11-67; 11-68). It extends as far as the rostral limit of the superior colliculus, and its cells are somewhat separated by fibers of the medial longitudinal fasciculus. The fibers that form the oculomotor nerve course ventrally through the midbrain tegmentum, medial to the red nucleus, with some fibers traversing that nucleus. They emerge ventrally from the midbrain into the interpeduncular fossa along the medial sulcus of the crus cerebri.

**RED NUCLEUS.** The red nucleus is a prominent structure of the midbrain tegmentum;

**FIG. 11-67.** Transverse section through mesencephalon at inferior colliculus. Nuclear groups represented diagrammatically in color. (From Villiger-Addison, courtesy of J. B. Lippincott Co.)

**FIG. 11-68.** Transverse section through mesencephalon at superior colliculus. Nuclear groups represented diagrammatically in color. (From Villiger-Addison, courtesy of J. B. Lippincott Co.)

it is located dorsomedial to the substantia nigra and just lateral to the descending fibers of the oculomotor nerve, some of which actually traverse the nucleus (Fig. 11-68). It has a reddish-pink color in freshly sectioned brains and its cells form a large egg-shaped mass extending from the lower limit of the superior colliculus caudally into the subthalamic region of the diencephalon rostrally. The human red nucleus is composed of a **parvocellular** (or neorubral) **portion** consisting principally of small- and medium-sized cells, and this is capped caudally by a large-celled component, the **magnocellular** (or paleorubral) **part**, which is more prominent in lower mammals but, nonetheless, clearly is present in man. Afferent projections to the red nucleus are derived mainly from the contralateral cerebellar nuclei by way of the superior cerebellar peduncle and from the ipsilateral precentral gyrus of the cerebral cortex. Efferent fibers from the red nucleus project to the spinal cord (rubrospinal), to the cerebellar nuclei (rubrocerebellar), and to certain brain stem structures (rubrobulbar), such as the facial nucleus, the motor nucleus of the trigeminal nerve, and the inferior olivary nucleus. The red nucleus also has connections with other brain centers, such as the thalamus, globus pallidus, and reticular formation, the details of which go beyond the purposes of this text.

**OTHER MIDBRAIN NUCLEI.** Other frequently described nuclear groups found in the midbrain tectum include the *dorsal tectal nucleus*, located dorsal to the nucleus of the trochlear nerve; the *ventral tectal nucleus*, found ventral to the medial longitudinal fasciculus; the *interpeduncular nucleus*, located just posterior to the interpeduncular fossa; the *interstitial nucleus* (of Cajal<sup>1</sup>), found in the rostral midbrain just lateral to the medial longitudinal fasciculus; the *nuclei of the posterior commissure*, located in the rostral midbrain in relation to that commissure; the *nucleus of Darkschewitsch*,<sup>2</sup> lateral and ventral to the cerebral aqueduct; and the *Edinger-Westphal nucleus*, located dorsal to the oculomotor nucleus.

### **Tectum of the Midbrain**

The mesencephalic **tectum** is the most dorsal part of the midbrain and is externally marked by four rounded eminences, the superior and inferior colliculi (or corpora quadrigemina), which project posteriorly from the **tectal** (or quadrigeminal) **plate**, a lamina of neural tissue that forms the dorsal

<sup>1</sup>Santiago Ramon y Cajal (1852-1934): A brilliant Spanish histologist and neuroanatomist (Madrid).

<sup>2</sup>Liverij O. Darkschewitsch (1858-1925): A Russian neurologist.

roof of the midbrain over the cerebral aqueduct (Fig. 11-64). The paired colliculi are situated rostral to the superior medullary velum and superior cerebellar peduncle and caudal to the third ventricle and posterior commissure. They are covered by the splenium of the corpus callosum and are partly overlapped on both dorsolateral sides by the pulvinar region of the posterior thalamus. The four colliculi are arranged in pairs, superior and inferior, and they are clearly demarcated and separated by a cruciate sulcus. The midline longitudinal part of this sulcus expands rostrally to form a slight depression in which is located the **pineal body** (Fig. 11-64). From the caudal end of the longitudinal sulcus, a white band—the **frenulum of the superior medullary velum**—is prolonged downward to the superior medullary velum. On either side of this band the trochlear nerve emerges from the brain stem and then passes ventrally on the lateral aspect of the superior cerebellar peduncle to the base of the brain (Fig. 11-54), coursing parallel to but between the superior cerebellar and posterior cerebral branches of the basilar artery.

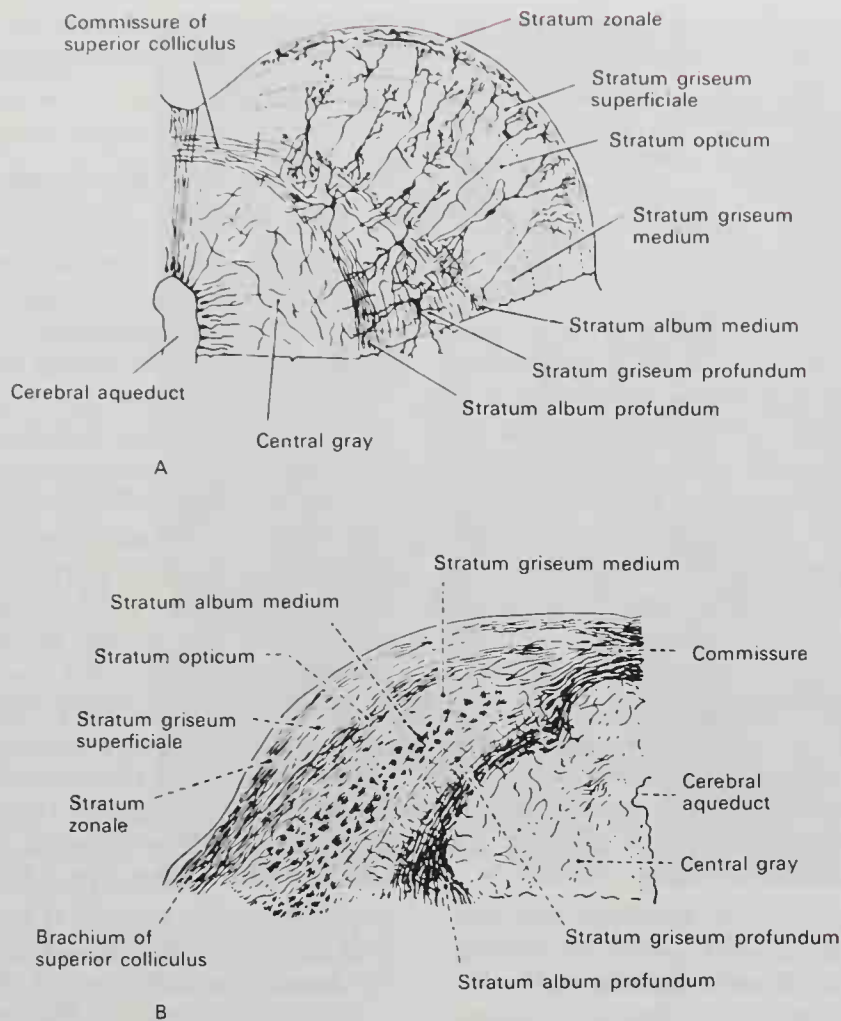

The **superior colliculi** are somewhat oval and larger and darker than the inferior colliculi (Figs. 11-54; 11-64). They serve primarily as reflex centers that alter the position of the eyes and head in response to sensory stimuli. The **inferior colliculi** have a hemispherical shape and are somewhat more prominent than the superior colliculi; they possibly function as auditory reflex centers as well as nuclei for the transmission of auditory signals to thalamic centers.

Extending ventrolaterally from the superior colliculus and passing between the pulvinar and medial geniculate body to reach the lateral geniculate body and the optic tract is the **brachium of the superior colliculus** (Fig. 11-64). It contains fibers from the optic tract, the lateral geniculate body, and the cerebral cortex that are destined for the superior colliculus. The **brachium of the inferior colliculus** is a thick band of tissue that passes rostrally and laterally from the inferior colliculus to the medial geniculate body (Fig. 11-64). It contains fibers of the auditory pathway from the lateral lemniscus and inferior colliculus to the medial geniculate body and possibly some fibers to and from the auditory cortex interconnecting with the inferior colliculus.

**INFERIOR COLLICULUS.** The inferior colliculi are two distinctive hemispherical neural masses that form the greater part of the caudal midbrain tectum (Figs. 11-54; 11-64). Internally, each inferior colliculus consists of an outer capsule of myelinated fibers and an inner oval mass of nerve cells called the **nucleus of the inferior colliculus**. More deeply located still is a thin layer of myelinated fibers interposed between the nucleus and the cerebral aqueduct.

The **nucleus of the inferior colliculus** (Fig. 11-67) is formed of medium and large-sized neurons that are densely packed and interconnected with the nucleus of the opposite inferior colliculus by way of a commissure that lies closer to the surface of the tectum than to the cerebral aqueduct. The **outer capsule** of myelinated fibers is formed principally of incoming projections of the lateral lemniscal pathway from the cochlear nuclei, the superior olive, and the trapezoid body. These fibers terminate on the cells of the nucleus of the inferior colliculus. They form the principal afferent pathway to the inferior colliculus and some of the lateral lemniscal fibers cross in the commissure to the inferior colliculus of the opposite side. Other incoming fibers to the inferior colliculus are derived from the ipsilateral medial geniculate body and from the auditory cortex. Connections with the superior colliculus also exist. Efferent fibers leave the inferior colliculus through its brachium to project to the ipsilateral medial geniculate body and even to the cerebral cortex. Other fibers from the inferior colliculus project back to relay nuclei in the auditory pathway, to the superior colliculus, as well as to the opposite inferior colliculus. The inferior colliculus functions as an important auditory center and may participate in the integration of auditory reflexes.

**SUPERIOR COLLICULUS.** The superior colliculi are two rounded elevations that form most of the rostral half of the mesencephalic tectum (Figs. 11-54; 11-64). The human superior colliculus is a complex laminated structure that reflects the anatomy of its inframammalian homologue, the optic lobe. Although it is difficult to generalize functional studies done in subhuman mammals to the functions served by the human superior colliculus, the available information indicates that the optic tectum is a center for the integration of visual, acoustic, and other envi-

**Fig. 11-69.** The laminae of the superior colliculus based on reconstruction from Golgi preparations (A) of an 8-month fetus to show the cellular organization, and of Weigert-stained adult brain (B) to show the myelinated fiber structure. (From M. B. Carpenter, *Human Neuroanatomy*, 7th ed., Williams and Wilkins, Baltimore, 1976.)

ronmental stimuli so that appropriate reactive movements of the eyes, head, and body can be made. Internally, the structure of the superior colliculus consists of alternating layers of gray substance and white matter. These laminae have been variously named, but the terms most frequently used today are the stratum zonale, stratum griseum superficiale (or stratum cinereum), the stratum opticum, and the stratum lemnisci (Fig. 11-69). Because the stratum lemnisci is frequently subdivided into four layers itself—the intermediate gray and white layers and the deep gray and white layers—it is not uncommon to describe the superior colliculus as consisting of seven strata.

The **stratum zonale** (I) is composed of fine, transversely coursing, myelinated and unmyelinated nerve fibers. These fibers form the external corticotectal pathway, which is derived principally from the occipital lobe

and enters the superior colliculus by way of its brachium. The **stratum griseum superficiale** (II), or superficial gray layer (frequently called stratum cinereum), is much thicker than the stratum zonale and it consists of many small multipolar nerve cells. The neurons are arranged in such a way that they receive terminals from both the overlying stratum zonale and the underlying stratum opticum, and their axons project inward to deeper layers. The **stratum opticum** (III) is a fiber-rich layer that is thinner in primates, including man, than in infraprimate mammals. The fibers are derived mostly from ganglion cells of the retina, enter the superior colliculus by way of its brachium, and terminate at least in the two adjacent gray layers—the superficial and intermediate gray layers.

The **stratum lemnisci** is subdivided into intermediate gray, intermediate white, deep

gray, and deep white layers. The **intermediate gray (IV)** and **intermediate white (V)** layers (stratum griseum medium and stratum album medium) are made up of masses of neurons and bundles of nerve fibers and they constitute important sites for the reception of corticotectal fibers from the occipital and preoccipital cortical regions. These fibers achieve the superior colliculus by way of the internal corticotectal pathway; they are importantly involved in the coordination of eye movements that allow the eye to follow a moving object across the field of vision. These layers also receive input from the spinal cord (spinotectal and spinothalamic paths), substantia nigra, and ventral thalamus. The **deep gray (VI)** layer and the **deep white (VII)** layer (stratum griseum profundum and stratum album profundum) are the strata closest to the periaqueductal gray substance. The deep gray layer consists of medium- to large-sized neurons that receive input from more superficial layers, while the deep white layer is composed of fibers that form the efferent paths from the superior colliculus (Fig. 11-69).

The superior colliculus receives afferent input from the retina, the cerebral cortex, the spinal cord, the ventral thalamus, the inferior colliculus, and the substantia nigra, while its efferent paths are distributed to the visual motor nuclei of the brain stem, the spinal cord, the pontine tegmentum, other sites in the midbrain, and the thalamus.

### ***Pretectal Region***

The pretectal region of the brain stem is the zone of transition between the midbrain and the diencephalon. It is located just rostral to the superior colliculus at the level of the posterior commissure, and its **pretectal nucleus** receives fibers from the optic tract on each side. The pretectal nucleus also receives input from the occipital and preoccipital regions of the cerebral cortex and possibly even from the frontal cortex. Efferent fibers leave the pretectal nucleus to terminate in the Edinger-Westphal nucleus.

The pretectal region is the important central relay station mediating the pupillary light reflex. This reflex is initiated by a bright light stimulus to the retina, and it is manifested through the parasympathetic elements in the oculomotor nerve that synapse in the ciliary ganglion. This parasympathetic

effect causes a contraction of the sphincter of the iris, thereby decreasing the diameter of the pupil.

### ***Blood Supply to the Cerebellum and Brain Stem***

The cerebellum and brain stem, including the midbrain, receive their blood supply by way of the vertebrobasilar arterial system. Each of the two **vertebral arteries** ascends in the deep neck from its origin on the posterior aspect of the subclavian artery, perforates the posterior occipitoatlantal membrane, and enters the posterior cranial fossa through the foramen magnum. On the lateral aspects of the first cervical segment of the spinal cord, the vertebral arteries pierce the dura mater at the level at which the first cervical nerves arise. The vessels then incline ventrally and medially and ascend nearly parallel to the longitudinally-oriented ventrolateral sulci of the medulla oblongata that separate the pyramids from the inferior olives. Each of the arteries passes ventral to the rootlets of the hypoglossal nerves; near or at the midline, ventral to the pontomedullary junction, the two vessels unite to form the **basilar artery** (Fig. 11-70).

One of the two vertebral arteries, more frequently the left, is larger than the other. The **posterior inferior cerebellar arteries** usually arise from the lateral aspects of the vertebral arteries before the two vertebrals join. Each vertebral artery also gives rise to a vessel that joins a similar branch from the other side to form the **anterior spinal artery**; likewise, the **posterior spinal arteries** arise from the vertebral arteries. The rami of the anterior spinal artery branch ventral to, while the posterior spinal arteries arise somewhat caudal to, the origins of the posterior inferior cerebellar arteries.

### ***BASILAR ARTERY***

The basilar artery ascends along the basilar sulcus on the ventral aspect of the brain stem from the pontomedullary junction to the rostral border of the pons, where the vessel divides into the **right and left posterior cerebral arteries** (Fig. 11-70). The paired **anterior inferior cerebellar arteries** branch from the basilar artery near the caudal border of the pons, and the two **superior cerebellar arteries** arise more rostrally near the

**Fig. 11-70.** Photograph of the human basilar artery and its branches seen on the ventral aspect of the pons. The junction of the vertebral arteries in this specimen is located slightly rostral to the pontomedullary junction. (From M. Takahashi, in *Radiology of the Skull and Brain: Angiography*, edited by T. H. Newton and D. G. Potts, Vol. 2, Book 2, C. V. Mosby, St. Louis, 1974.)

pontomesencephalic junction, just behind the point at which the basilar artery divides into the posterior cerebral arteries. Often the course of the basilar artery is tortuous or curved and it may show an S-shaped ascent on the ventral pons, in which case it may slightly deviate from the midline. Its length varies from about 2.5 cm to nearly 4.0 cm and its average diameter is about 4.1 mm (Busch, 1966).

Between the origins of the anterior inferior and superior cerebellar arteries, the basilar artery gives off a large number of transversely coursing **pontine branches** that supply the pons and lowest parts of the midbrain (Fig. 11-70). Penetrating branches derived from the vertebral arteries, the upper part of the anterior and posterior spinal arteries, and small vessels from the posterior inferior cerebellar arteries supply the medulla oblongata. Most of the arteries supplying the brain stem from these parent vessels are unnamed, but they can be categorized as **median** (or paramedian) **branches** (see Figs.

11-74 to 11-79), which almost immediately penetrate the ventral median zone of the brain stem as they emerge from the larger arteries, and as the longer coursing **circumferential branches**, which pass laterally around the brain stem and from which short penetrating rami supply the paramedian, lateral, and dorsal zones of the brain stem (Gillilan, 1972). Usually four to six pairs of circumferential arteries branch from the lateral aspects of the basilar artery to supply the pons (Kaplan and Ford, 1966). The basilar artery also gives rise to the paired **labyrinthine arteries**, which course laterally and enter the internal acoustic meatus on each side to supply the vestibulocochlear and facial nerves, but do not contribute any blood supply to the brain stem.

#### BLOOD SUPPLY TO THE CEREBELLUM

The cerebellum receives its blood supply from three paired arterial branches that arise from the vertebrobasilar system: the

posterior inferior cerebellar arteries, the anterior inferior cerebellar arteries, and the superior cerebellar arteries. Although there is some variation in the origin and course of these vessels, it is fair to say that most blood to the cerebellum comes by way of the vertebral and basilar arteries. The posterior communicating arteries, which link the vertebro-basilar system with the carotid system anteriorly, may be significant vessels, but they are usually small and their average diameter is less than 1 mm (Wollschlaeger and Wollschlaeger, 1974).

#### POSTERIOR INFERIOR CEREBELLAR ARTERY.

The posterior inferior cerebellar artery usually arises from the vertebral artery and supplies much of the medulla oblongata, as well as the lower part of the floor of the fourth ventricle and its choroid plexus, and much of the inferior aspect of the cerebellum, including the inferior vermis, inferior semilunar lobule, biventer lobule, and tonsil (Figs. 11-71; 11-76). It also supplies the dentate, interpositus, and fastigial nuclei of the cerebellum, in addition to sending branches to the inferior cerebellar peduncle.

The origin and course of the posterior inferior cerebellar artery vary. Commonly, it branches from the vertebral artery on each side, about 1.5 cm below the junction of the two vertebrals, and usually it arises rostral (about 1 cm) to the foramen magnum (Fig. 11-71). The vessel may arise, however, lower on the vertebral artery or closer to the vertebral junction, or even from the basilar artery itself. It may be absent (15 to 20%), in which case the territory of the posterior inferior artery is usually supplied by the anterior inferior cerebellar artery (Margolis and Newton, 1974).

From its origin, the posterior inferior cerebellar artery courses laterally and superiorly between the rootlets of the hypoglossal and vagus nerves and across the inferior cerebellar peduncle, along the groove between the lateral aspect of the medulla and the cerebellum (Fig. 11-71). As it approaches the lateral angle of the fourth ventricle, it makes a loop around the lateral ventricular aperture (foramen of Luschke), adjacent to the cerebellar tonsil. It then becomes directed once again between the brain stem and the cerebellar surface, sending branches to both the choroid plexus of the fourth ventricle and the inferior surface of the cerebellum.

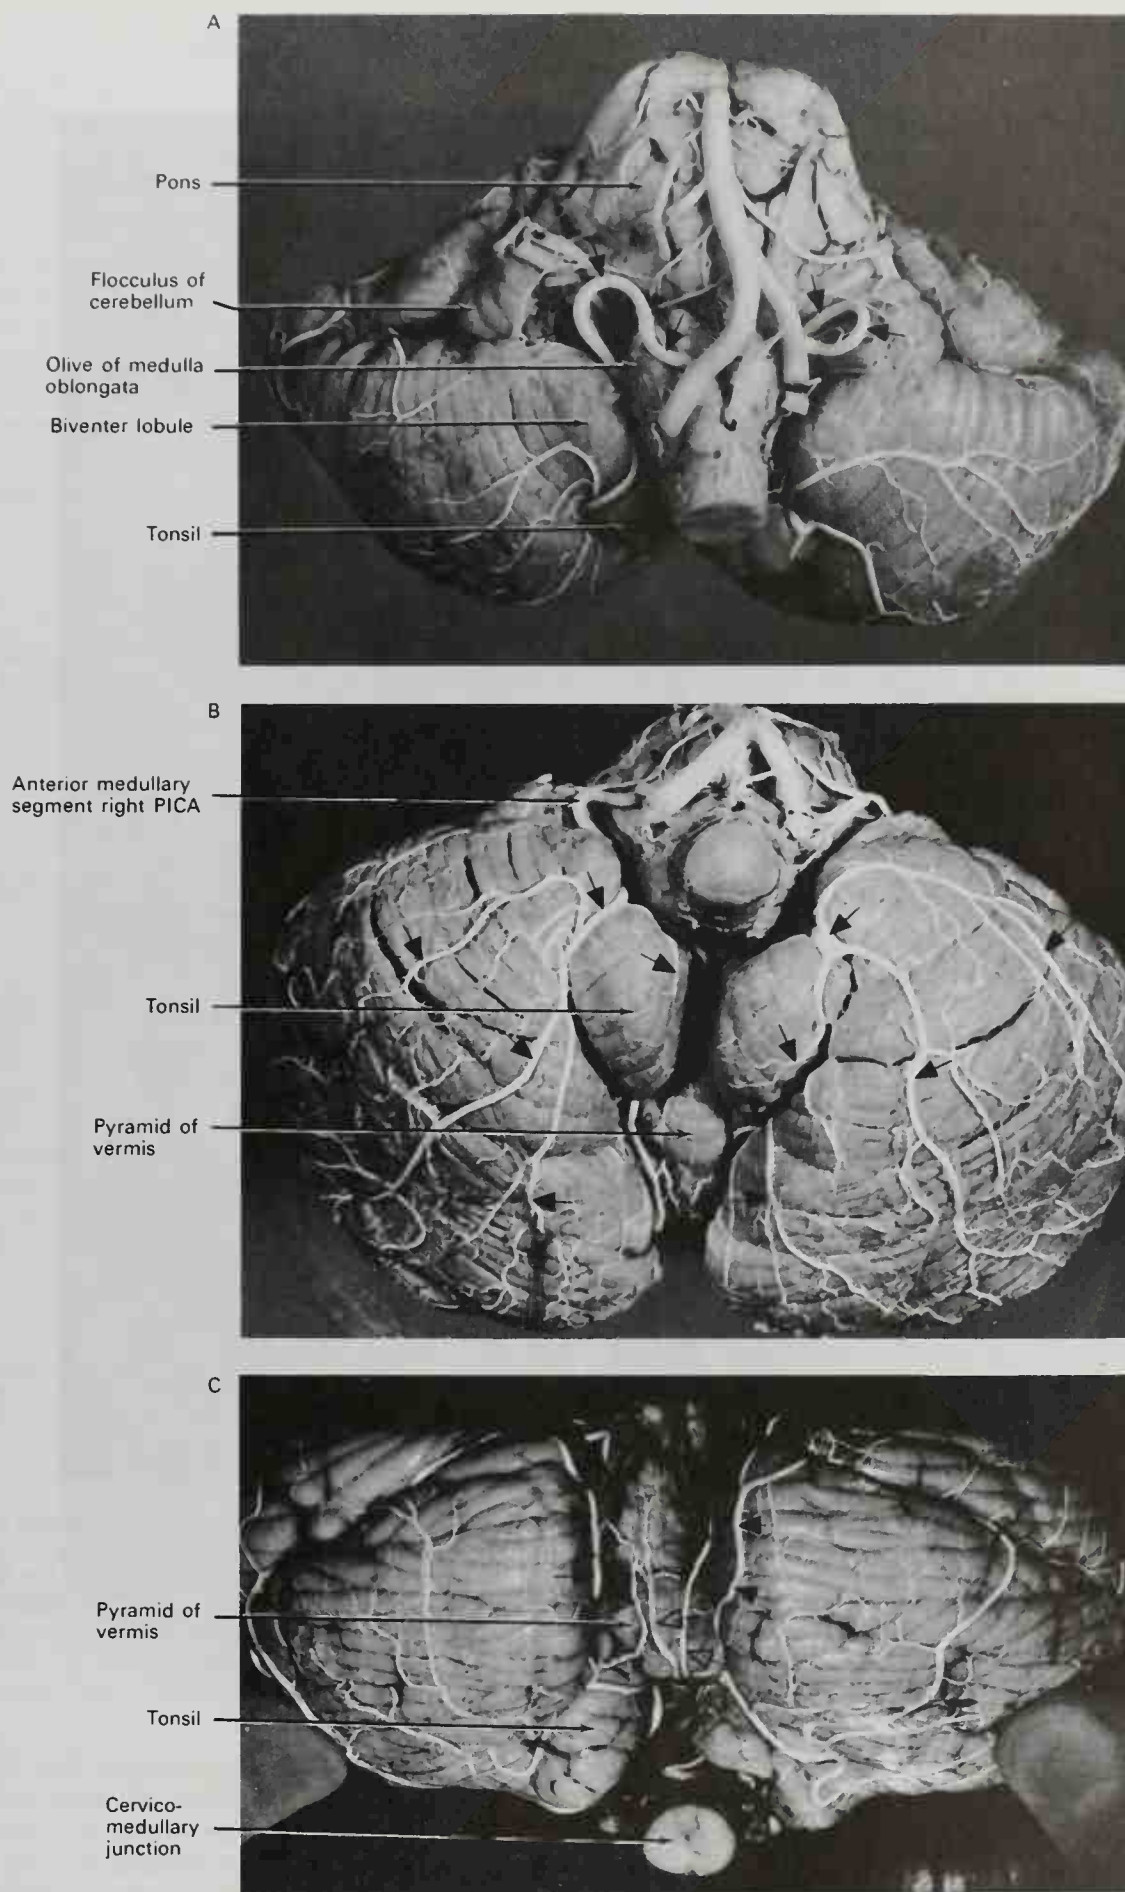

In addition to the many small branches of

the posterior inferior cerebellar artery that supply the posterior and lateral aspects of the medulla, its terminal branches include the lateral and medial tonsillohemispheric branches, which course along the inferior surface of the cerebellar hemispheres, and the vermis branches, which course medially along the inferior vermis (Fig. 11-71, B). The **lateral and medial tonsillohemispheric branches** of the posterior inferior cerebellar artery supply the tonsil, the biventer lobule, and much of the inferior semilunar lobule. The **vermis branches** course along the cerebellar vallecule between the vermis and the cerebellar hemisphere and supply much of the inferior vermis from the tuber vermis to the uvula (Fig. 11-71, C).

#### ANTERIOR INFERIOR CEREBELLAR ARTERY.

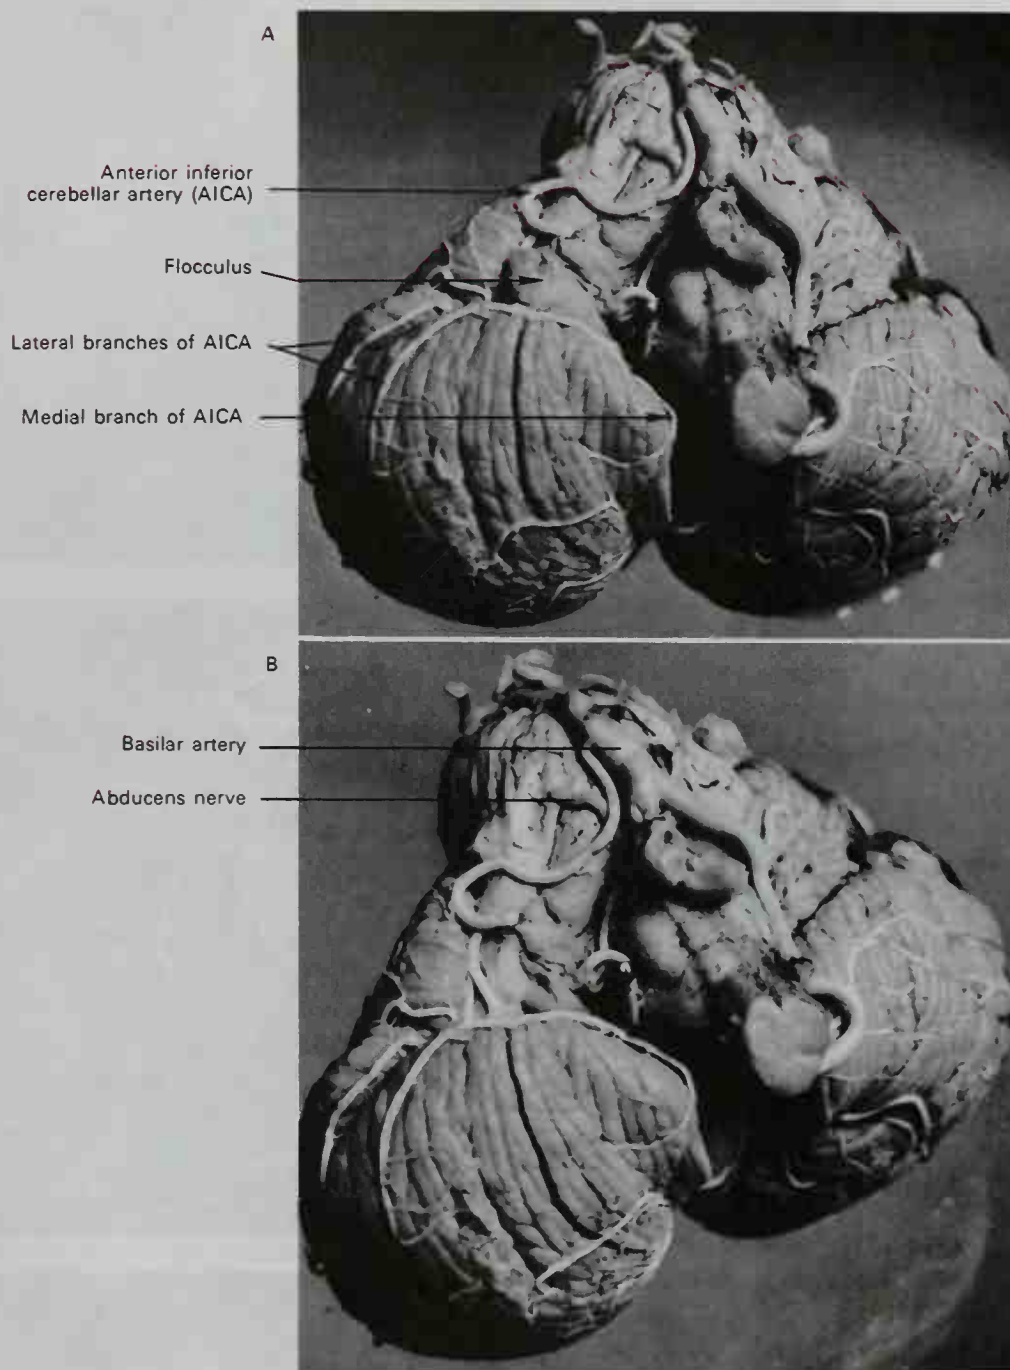

The anterior inferior cerebellar artery arises from the basilar artery but its precise site of branching from the main trunk varies. Most commonly (about 75%), it arises from the lower third of the basilar artery about 1 cm above the union of the two vertebral arteries (Fig. 11-72). The manner by which the paired vessels arise and their comparative size also vary. Frequently, the anterior inferior cerebellar artery and the labyrinthine artery arise as a common stem. When the vessels of the two sides are uneven in size, there is a compensatory enlargement or diminution in the size of the corresponding posterior inferior cerebellar artery (Atkinson, 1949).

From its site of origin, the anterior inferior cerebellar artery courses laterally and somewhat caudally on the ventral surface of the pons, just above the sulcus marking the pontomedullary junction. It lies more frequently ventral than dorsal to the abducens nerve (Fig. 11-72), and it passes to the pontocerebellar angle ventral to the facial and vestibulocochlear nerves also. In its course toward the cerebellum, it gives off fine branches to the pons, root branches to the nearby cranial nerves, a branch to the choroid plexus, and an anastomotic branch to the posterior inferior cerebellar artery. Beyond the cerebellopontine angle, the anterior inferior cerebellar artery sends **lateral and medial branches** to supply the flocculus, the biventer lobule, and the inferior semilunar lobule, as well as the middle and inferior cerebellar peduncles (Fig. 11-72). If the posterior inferior cerebellar artery is small, the region supplied by the anterior inferior cerebellar artery is reciprocally larger.

**FIG. 11-71.** The posterior inferior cerebellar artery. A, Solid black arrows point to the posterior inferior cerebellar arteries, which arise symmetrically from the vertebrals on the two sides. B, Shows the distribution of the tonsillohemispheric branches (black arrows) of the posterior inferior cerebellar arteries on the inferior surface of the cerebellum. C, The vermis branches of the posterior inferior cerebellar arteries are indicated by the open arrows and the medial tonsillohemispheric branches are identified by the solid black arrows. (From M. T. Margolis and T. H. Newton, in *Radiology of the Skull and Brain: Angiography*, edited by T. H. Newton and D. G. Potts, Vol. 2, Book 2, C. V. Mosby, St. Louis, 1974.)

**Fig. 11-72.** Pictured here is the anterior inferior cerebellar artery (AICA) and its relationship to the ventral aspect of the brain stem and inferior surface of the cerebellum. Note that the two vertebral arteries join to form the basilar artery and that the right (reader's left) AICA arises from the basilar artery. A, The AICA is partially hidden by the flocculus, but its lateral and medial branches can be seen. B, The flocculus has been removed. Note also that the AICA courses ventral to the abducens nerve in this specimen. (From M. Takahashi, in *Radiology of the Skull and Brain: Angiography*, edited by T. H. Newton and D. G. Potts, Vol. 2, Book 2, C. V. Mosby, St. Louis, 1974.)

**SUPERIOR CEREBELLAR ARTERY.** The superior cerebellar arteries (Fig. 11-73) arise from the basilar artery several millimeters caudal to the division of the basilar trunk into the posterior cerebral arteries. At times the vessels may be duplicated on one or even both sides. The vessel's course on each side initially parallels that of the posterior cerebral

artery, from which it is separated by the oculomotor nerve. Directed at first laterally from their origins, the superior cerebellar arteries then encircle the brain stem at the level of the pontomesencephalic junction to achieve the dorsal aspect of the neuraxis (Fig. 11-73). Along this course around the upper pons, perforating arteries are supplied

to the pons and lower midbrain, including the crus cerebri, and anastomoses are effected rostrally with branches of the posterior cerebral arteries. In order to supply the cerebellar lobules and vermis of the superior part of the cerebellum, each superior cerebellar artery divides into marginal and hemispheric (sometimes called cortical) branches, which are directed laterally over the superior cerebellar surface, and the superior vermis branches, which are more medially oriented.

The **marginal branch** frequently arises from the superior cerebellar artery on the lateral aspect of the pons (Fig. 11-73). It continues to course posteriorly, alongside the main trunk of the artery, and then it turns acutely laterally to reach the upper lateral margin of the cerebellum. Just above the horizontal fissure of the cerebellum, the marginal branch courses backward to supply the lateral portions of the quadrangular lobule, lobulus simplex, and superior semilunar lobule. Two or three **hemispheric**

**Fig. 11-73.** The superior cerebellar artery (SCA). The superior surface of the cerebellum and the transversely severed upper pons are viewed from above. A, Observe the two superior cerebellar arteries branching from the basilar artery, encircling the brain stem, and dividing into marginal, hemispheric, and vermis branches on the superior surface of the cerebellum. B, Roentgenogram of the specimen in A. (From H. B. Hoffman, M. T. Margolis, and T. H. Newton, in *Radiology of the Skull and Brain: Angiography*, edited by T. H. Newton and D. G. Potts, Vol. 2, Book 2, C. V. Mosby, St. Louis, 1974.)

**Fig. 11-74.** Angiogram of the midbrain, pons, and medulla seen in a longitudinal section of the human brain stem along the midline. Note the different angles formed by the median arteries as they supply the different levels. In the lower midbrain and upper pontine regions they course more caudally; in the midpontine region they converge toward the fourth ventricle at nearly right angles, while in the caudal pons and upper medulla the vessels are oriented in a somewhat rostral direction. (From O. Hassler, *Neurology*, 17: 368-375, 1967.)

**branches** of the superior cerebellar artery arise beyond the origin of the marginal branch (Fig. 11-73). After reaching the superior cerebellar surface, they course backward over the cerebellar cortex to supply the medial two-thirds of all the lobules superior to the horizontal fissure. Finally, each superior cerebellar artery terminates dorsally and medially in two or three **superior vermis branches** (Fig. 11-73, A). These course backward along the upper surface of the superior vermis, close to the midline, and send penetrating branches into the superior vermis from the lingula rostrally to the folium vermis caudally.

#### BLOOD SUPPLY TO THE BRAIN STEM

The blood supply to the medulla, pons, and midbrain is derived from **median arteries** that pierce the ventral brain stem near its midline and from other vessels that penetrate the brain stem more laterally and dorsally (Fig. 11-74). In this manner, a pattern of four zones has been described that can be generalized for cross sections of the brain stem at any level. These zones are a **median zone**, which is supplied by the median arteries that enter the brain stem ventrally near the midline, and the **paramedian, lateral, and dorsal zones**, which are supplied by vessels that pierce the brain stem ventrolaterally, laterally, and dorsolaterally re-

spectively (Fig. 11-75). These vessels may be circumferential branches coursing around the brain stem from their origin ventrally, or they may be short penetrating arteries derived from larger named vessels coursing through the region.

**MEDULLA OBLONGATA.** The median zone of the entire medulla oblongata receives its blood supply by way of median vessels that branch from the anterior spinal artery (Fig. 11-76). The paramedian and lateral regions of the lower medulla also receive penetrating vessels from the vertebral artery. Likewise, the paramedian zone of the upper half of the medulla receives its branches from the vertebral artery. The dorsal region of the medulla receives its penetrating arteries by way of the posterior spinal arteries and by way of the posterior inferior cerebellar arteries (Fig. 11-77).

**PONS.** The pons is supplied by median, short circumferential, and long circumferential branches of the basilar artery, as well as by dorsolaterally penetrating branches from the anterior inferior cerebellar artery and the superior cerebellar artery (Fig. 11-78). Thus, the median zone of the pons receives median penetrating branches from the basilar artery that enter the basilar sulcus of the ventral brain stem near the midline. The paramedian zone receives the short circumferential branches of the basilar artery, which initially course to the ventrolateral

**FIG. 11-75.** Diagrammatic cross sections through the brain stem illustrating representative levels of the medulla (lower two), pons (middle two), and midbrain (uppermost two) on the left, and the four intrinsic arterial zones on the right. Cross sections to be compared with those in Figures 11-77 to 11-79. Vertical lines, median zone; horizontal lines, paramedian zone; stippled region, lateral zone; cross-hatched region, dorsal zone. (From L. A. Gillilan, in *Handbook of Clinical Neurology*, edited by J. P. Vinken and G. W. Bruyn, American Elsevier, New York, 1972.)

aspect of the pons before piercing the neural tissue. The lateral zone in the lower pons is supplied by lateral penetrating branches of the anterior inferior cerebellar artery; in the midpontine region, the lateral zone receives long circumferential branches of the basilar artery, and in the upper pontine region, it receives penetrating branches from the superior cerebellar artery. No large dorsal

zone comparable to that seen in the lower medulla and midbrain exists in the pons because of the position of the fourth ventricle, but its dorsolateral region is also reached by long circumferential vessels from the basilar artery or by penetrating branches from the superior cerebellar artery.

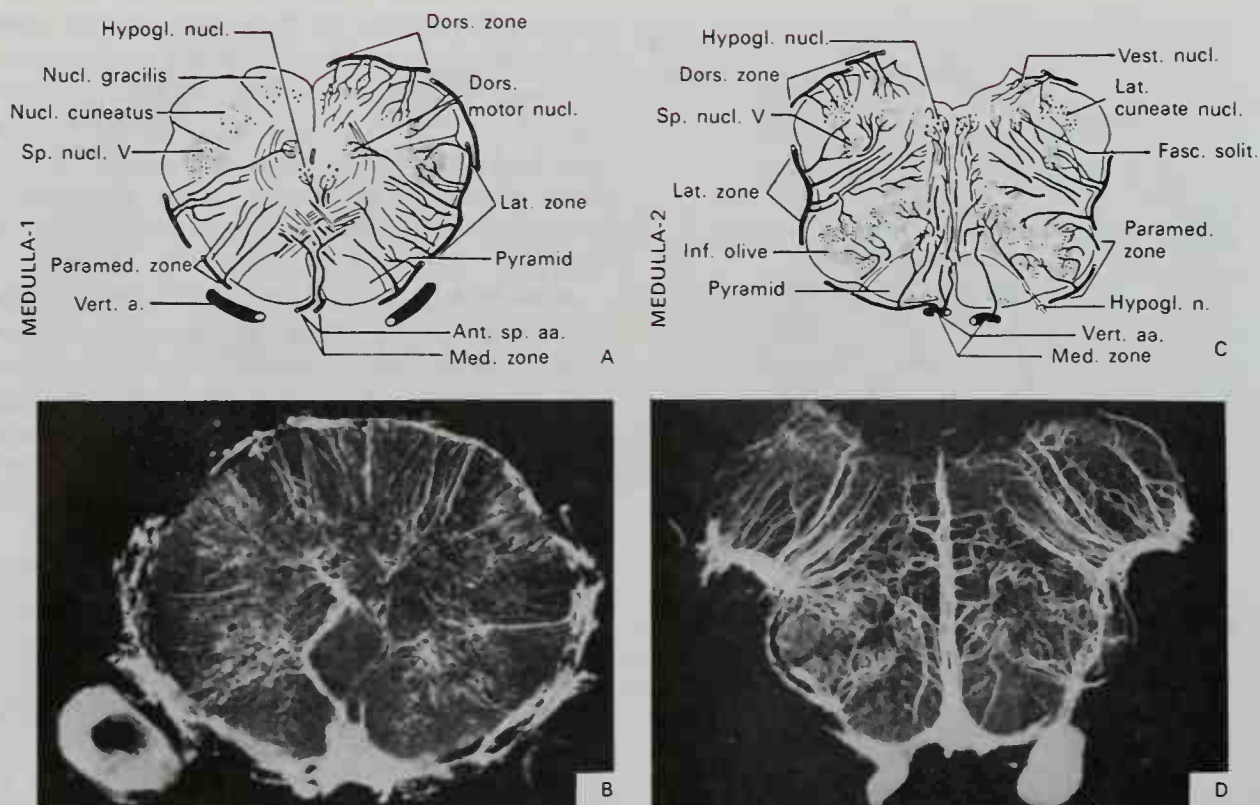

**MIDBRAIN.** The mesencephalon receives its arterial supply through branches derived mostly from the superior cerebellar artery and the posterior cerebral artery, but some vessels from the posterior communicating arteries and from the posterior choroidal branch of the posterior cerebral artery also supply it.

The median zone of the midbrain receives its median penetrating branches from three sources: the basilar artery at its point of bifurcation, the proximal parts of the two posterior cerebral arteries, and the posterior communicating arteries (Fig. 11-79). The paramedian zone of the mesencephalon receives short circumferential arteries and penetrating branches from the proximal parts of the posterior cerebral and superior cerebellar arteries. The lateral mesencephalic region also receives long circumferential branches from the posterior cerebral arteries and penetrating branches from the superior cerebellar artery as that vessel courses around the midbrain (Fig. 11-80). The dorsal or tectal zone of the midbrain receives long circumferential branches from the posterior cerebral artery, penetrating branches from the superior cerebellar artery, and other penetrating branches from the posterior choroidal branch of the posterior cerebral artery.

#### VENOUS DRAINAGE OF THE BRAIN STEM AND CEREBELLUM

The veins that drain the substance of the brain are thin-walled and contain no valves. Venous blood courses toward the surface where the venous channels are frequently more superficial to the arterial vessels. These usually drain into larger named channels, which eventually flow into the sinuses of the dura mater. For the most part, venous blood from the posterior cranial fossa leaves the cranial cavity by way of the internal jugular vein or the basilar plexus, which flows caudally into the internal vertebral plexus of veins within the spinal column.

**FIG. 11-76.** The intrinsic arterial blood supply to the medulla oblongata. A, Diagrammatic representation of the median and other penetrating vessels supplying the median, paramedian, lateral, and dorsal zones of the medulla at the level of the nuclei gracilis and cuneatus. B, Angiogram of the medulla about 2.0 cm below the pontomedullary junction. Note that the median artery bends around the decussation of the pyramids. C, Schema of the intrinsic arteries at the level of the inferior olive in the more rostral medulla. D, Angiogram taken in the upper part of the medulla 3 to 7 mm below the pontomedullary junction. (A and C from L. A. Gillilan, 1972; B and D from O. Hassler, 1967.)

**FIG. 11-77.** The dorsal aspect of the medulla oblongata at the level of the obex, viewed from above with the cerebellum elevated and its hemispheres spread apart. Observe the penetrating branches of the posterior inferior cerebellar arteries supplying the dorsolateral medulla (solid arrows) and other branches (open arrows) supplying the tela choroidea. (From M. T. Margolis and T. H. Newton in *Radiology of the Skull and Brain: Angiography*, edited by T. H. Newton and D. G. Potts, Vol. 2, Book 2, C. V. Mosby, St. Louis, 1974.)

**FIG. 11-78.** The intrinsic arterial blood supply to the pons. A and B, Diagrammatic cross sections of the pons at the level of the abducens nucleus (A) and more rostrally (B), showing its median and other penetrating arteries, which supply the median, paramedian, lateral, and dorsal zones. C, Angiogram of the pons seen in cross section about 1 cm below the pontomesencephalic border. (A and B from L. A. Gillilan, 1972; C from O. Hassler, 1967.)

**FIG. 11-79.** The intrinsic arterial blood supply to the midbrain. A and B, Diagrammatic cross sections of the midbrain at the level of the inferior colliculus (A) and superior colliculus (B), showing the blood supply to the median, paramedian, lateral, and dorsal zones. C, Cross section of an angiogram of the midbrain, about 4 mm above the pontomesencephalic border. (A and B from L. A. Gillilan, 1972; C from O. Hassler, 1967.)

**BRAIN STEM.** Most of the blood from the substance of the midbrain drains laterally and anteriorly into the basal vein; however, venous drainage from the dorsal midbrain region is into the great cerebral vein. Venous

drainage from the pons is into superficial plexuses, which then drain laterally and ventrally into the inferior petrosal sinuses and the basilar plexus of veins in the floor of the cranial cavity. Venous blood from the

**Fig. 11-80.** In this specimen (viewed from above), the brain stem has been severed near the pontine-mesencephalic junction. Observe the multiple perforating (penetrating) branches of the superior cerebellar arteries, which supply the median, paramedian, and lateral zones of the upper pons and lower midbrain. (From H. B. Hoffman, M. T. Margolis, and T. H. Newton in *Radiology of the Skull and Brain: Angiography*, edited by T. H. Newton and D. G. Potts, Vol. 2, Book 2, C. V. Mosby, St. Louis, 1974.)

medulla oblongata drains into the anterior and posterior spinal veins inferiorly, as well as into the occipital and basilar sinuses.

**CEREBELLUM.** The veins from the substance of the cerebellum drain toward the cerebellar surfaces to form superior and inferior median veins that drain the vermal regions and the medial portions of the cerebellar hemispheres. The superior median vein drains into the great cerebral vein, while the inferior median vein flows into the straight sinus. The veins on the more lateral

aspects of the superior and inferior cerebellar surfaces drain into the transverse, superior petrosal, and occipital sinuses.

### THE DIENCEPHALON

The **diencephalon** is the region of the brain that is interposed between the mesencephalon, or uppermost part of the brain stem, and the **telencephalon**, which consists principally of the greatly expanded cerebral hemispheres (Figs. 11-81; 11-82). Together,

the diencephalon and telencephalon form the **prosencephalon**, which develops from the forebrain vesicle around a cavity that is to become the **third ventricle** and its intercommunicating lateral ventricles. The upper surface of the diencephalon is concealed beneath the corpus callosum and is covered by a fold of pia mater called the tela choroidea of the third ventricle; inferiorly the diencephalon reaches the base of the brain. The diencephalon extends from the pretectal region caudally, just behind the mammillary bodies and at the level of the posterior commissure, to a plane rostrally as far as the interventricular foramen and optic chiasma. On each side the diencephalon is separated from other prosencephalic structures situated laterally and rostrally by the internal capsule (Fig. 11-84). Also located dorsolaterally are the tail of the caudate nucleus and the stria terminalis. The right and left halves of the diencephalon are separated by the narrow, vertically oriented, slit-like cavity of the third ventricle, with the exception of the **interthalamic adhesion**, which is located just caudal to the interventricular foramen, where the two median surfaces are frequently, but not always, joined (Fig. 11-84).

Coursing longitudinally along the lateral wall of the third ventricle is the **hypothalamic sulcus**. This sulcus, which can best be seen in a median sagittal view of the forebrain, extends forward from the lateral wall of the cerebral aqueduct at the level of the posterior commissure and to the rostral end of the diencephalon as far as the interventricular foramen (Fig. 11-82). Serving as an anatomic landmark and perhaps even as the rostral extension of the sulcus limitans separating the alar and basal plates, the hypothalamic sulcus divides the diencephalon on each side into dorsal and ventral parts. The **dorsal part of the diencephalon** consists of the **dorsal thalamus** (frequently referred to simply as the **thalamus**), the **metathalamus**, consisting of the medial and lateral geniculate bodies, and the **epithalamus**; the **ventral part of the diencephalon** includes the **subthalamus** and the **hypothalamus**.

### **Dorsal Thalamus**

On each side the dorsal thalamus consists of a large ovoid mass about 4 cm long that forms most of the lateral wall of the third ventricle and extends caudally for some dis-

tance beyond that cavity. Its external form can be described as consisting of anterior and posterior extremities and of superior, medial, inferior, and lateral surfaces (Fig. 11-83). The medial and superior thalamic surfaces are exposed to the ventricles, whereas the inferior and lateral surfaces lie adjacent to other neural structures.

The **anterior or rostral extremity** is narrow, lies close to the midline, and on each side forms the posterior boundary of the interventricular foramen.

The **posterior extremity** is expanded and, on each side, directed backward and laterally to extend over the superior colliculus and its brachium. The **pineal body** is situated between the two rounded, medially prominent, posterior portions called the **pulvinars**. The inferolateral aspect of the posterior extremity presents an oval swelling, the **lateral geniculate body**, while beneath the pulvinar and separated from it by the brachium of the superior colliculus is the **medial geniculate body**. The geniculate bodies constitute the metathalamus.

The **superior or dorsal surface** (Fig. 11-81) is slightly convex and freely adjoins the ventricular cavities. It is covered by a layer of white matter called the **stratum zonale** and is separated laterally from the caudate nucleus by a band of white fibers, the **stria terminalis**, and by the **thalamostriate vein**. The superior surface is divided into medial and lateral parts by an oblique shallow furrow that corresponds in position to the lateral margin of the overlying fornix. The broader lateral part of the superior surface forms the floor of the lateral ventricle and is covered by the ependymal lining of that cavity. The narrower medial part is covered by the tela choroidea of the third ventricle, which also separates it from the overlying fornix. Anteriorly, the superior surface is separated from the medial surface by a raised ridge formed by the reflection of the ependyma of the third ventricle, called the **taenia thalami**, which becomes slightly more emphasized by the underlying **stria medullaris thalami**. Posteriorly, the taenia thalami and stria medullaris converge toward the midline near the stalk of the **pineal body** (Fig. 11-81).

The **inferior surface** of the thalamus rests on and is continuous with the upward prolongation of the tegmentum of the midbrain, the subthalamus; more rostrally, it rests on the hypothalamus.

**Fig. 11-81.** A horizontal section through both cerebral hemispheres, exposing the dorsal thalamus and the third ventricle as viewed from above. Most of the corpus callosum, along with the columns of the fornix and the tela choroidea of the third ventricle, has been removed. The left temporal lobe has been dissected as deep as the inferior horn of the lateral ventricle, thereby exposing more completely the hippocampal formation. (After Sobotta.)

The protruding medial surface of the thalamus on each side constitutes the upper part of the lateral walls of the third ventricle. As mentioned previously, the two medial surfaces are frequently joined by a flattened gray band, the interthalamic adhesion (formerly called the massa intermedia). This surface is also marked by the longitudinally oriented hypothalamic sulcus.

The lateral surface of the thalamus is in contact with a thick band of white fibers that forms the occipital part or posterior limb of

the internal capsule; the thalamus is thereby separated from the lentiform nucleus of the corpus striatum.

**GENERAL STRUCTURE AND NUCLEAR GROUPS.** The thalamus consists chiefly of gray substance, but its superior surface is covered by a layer of white substance, named the **stratum zonale**. Laterally, next to the reticular nucleus and the internal capsule, lies a similar thin layer of white substance termed the **external medullary lamina**. Internally, the thalamic gray substance

**Fig. 11-82.** A midsagittal section through the brain in the region of the diencephalon and midbrain, showing the thalamic and hypothalamic structures that bound the third ventricle. Note the cerebral aqueduct interconnecting the fourth ventricle with the third ventricle. (From E. C. Crosby, T. Humphrey and E. W. Lauer, *Correlative Anatomy of the Nervous System*. The Macmillan Co., New York, 1962.)

is subdivided into three parts—**anterior**, **medial**, and **lateral**—by a vertical septum of white matter, the **internal medullary lamina**. As this septum passes forward, it bifurcates and then partially surrounds the anterior thalamic region. Although each of the three principal thalamic parts contains large neuronal masses, they are further subdivided into smaller nuclear groups to facilitate their description and understanding. The plans by which the thalamic nuclei have been subdivided vary somewhat according to different authors, but generally the nuclear groups

can be listed as follows: **anterior**, **midline**, **medial**, **intralaminar**, **lateral**, **ventral**, and the **thalamic reticular nucleus** (Fig. 11-83).

#### NUCLEI OF THE DORSAL THALAMUS

**ANTERIOR THALAMIC NUCLEI.** There are three nuclei usually described in the anterior group: **anterior dorsal**, **anterior ventral**, and **anterior medial**; they form a distinct knob-like swelling on the anterior dorsal surface of the thalamus called the **anterior thalamic tubercle** (Fig. 11-81). The anterior

ventral nucleus is the largest of the nuclei in the anterior group, and the group as a whole is separated from the remainder of the thalamus by the diverging limbs of the **internal medullary lamina**. The distinctness of the three nuclei in the anterior group is more marked in lower animals, but in the subhuman primate and in the human thalamus, the demarcation between the anterior ventral and anterior medial nuclei is less clear. The anterior dorsal nucleus forms a long, narrow group of cells on the dorsomedial surface of the anterior ventral nucleus.

The anterior thalamic nuclei receive fibers from the mammillary bodies by way of the mammillothalamic tracts (Fig. 11-84) and probably send some thalamomammillary fibers back to the mammillary bodies in the same bundle. They also receive large numbers of fibers directly from the fornix and communicate intrathalamically with nuclei in both the medial and lateral thalamic groups. Thalamocortical efferent fibers from the anterior nuclei project to areas 23, 24, and 32 of the cingulate gyrus by way of the anterior limb of the internal capsule. Thus, the anterior nuclei form a relay station for impulses from the mammillary bodies to the cingulate gyrus; corticothalamic fibers also project back to the anterior nuclei from the cingulate gyrus. Other fibers from the cingulum course to the entorhinal cortex, which in turn projects to the hippocampus. Impulses coursing along this latter path could subsequently influence cells in the anterior nucleus by way of the fornix-mammillary body-mammillothalamic path.

**MIDLINE NUCLEI.** The nuclei of the midline (Fig. 11-83) consist of clusters of cells that form the periventricular gray substance bordering the third ventricle; they also contribute to the structure of the interthalamic adhesion. They are considerably less well developed in the thalami of subhuman primates and man than in those of lower vertebrates, where, in fact, they form a large part of the thalamus. In the human thalamus, small nuclear masses representative of the more prominent nuclei in submammalian species can frequently be recognized. These

include the **parataenial nucleus**, found ventral and medial to the stria medullaris; the **paraventricular nuclei** (anterior and posterior), juxtaposed to the third ventricle on the dorsomedial wall of the thalamus; and remnants of the **nucleus reuniens**, **nucleus centralis medialis**, and the **nucleus rhomboidalis**, located near or within the interthalamic adhesion.

The midline nuclei have some interconnections with the preoptic and hypothalamic zones ventral to the thalamus and with other nuclei of the thalamus, such as the dorsomedial nucleus and the nuclei of the intralaminar group. In lower forms, where the midline nuclei are better developed, there appears to be evidence of interconnections with the corpus striatum and probably with other regions of the neuraxis as well. Although much more needs to be learned about the anatomy and physiology of these phylogenetically old structures, there is conjecture that they may in some manner be related to other structures in the brain that assist in the regulation of visceral functions.

**MEDIAL NUCLEI.** The medial thalamic nuclear group (Fig. 11-83) consists of those cellular masses that are bounded laterally by the internal medullary lamina and medially by small collections of neurons that lie adjacent to the third ventricle. The nucleus medialis dorsalis (frequently called the dorsomedial nucleus) is the largest of the nuclei in this group; it is a prominent mass of cells that extends rostrocaudally for a distance of nearly 2 cm. In some descriptions, the centromedian, parafascicularis, paracentralis, and centralis lateralis nuclei are included in the medial group; however, they are classified in the intralaminar nuclear group in this account. Thus, from this nuclear group, only the nucleus medialis dorsalis is detailed further.

The **nucleus medialis dorsalis** (Fig. 11-85) consists of a magnocellular portion, containing relatively large polygonal cells located rostromedially, and a parvocellular part, containing clusters of small cells found caudolaterally. This nucleus is more prominent in primates than in lower forms. It be-

**Fig. 11-83.** Diagrammatic representations of the human thalamus, showing the principal nuclei from a dorsal view (A) and a medial view (B). The anterior, midline and medial nuclei are shown as groups: Dark blue in A and dark gold in B; Nuclei that project to association regions of the cerebral cortex: Light blue in A and yellow in B; Specific relay nuclei: Orange in A and purple in B. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Urban and Schwarzenberg, Munich, 1980.)

gins rostrally near the level of the anterior medial nucleus and extends caudally as far as the habenular complex. It is known to interconnect with the nucleus centromedianus, the amygdala, the parolfactory area, the anterior perforated substance, and the corpus striatum. Its interconnections with the hypothalamus, preoptic region, and especially the frontal cortex, however, are most significant. The medial portion of the nucleus medialis dorsalis both receives and sends fibers to the preoptic region and to the hypothalamus by way of the diencephalic periventricular system, and it also has connections with cortical areas 11 and 12 on the orbital surface of the frontal lobe. Profuse projections from the parvocellular portion of the nucleus medialis dorsalis are directed by way of the inferior thalamic radiation to the entire prefrontal cortex on the lateral surface of the cerebral hemisphere (areas 10, 11, 44, 45, 46, and 47), as well as to the cortex of the temporal operculum (areas 40 and 42). Likewise, there are massive corticothalamic projections to the nucleus medialis dorsalis from the prefrontal cortex.

**INTRALAMINAR NUCLEI.** The intralaminar nuclei are so designated because they are cellular groups that anatomically are adjacent to or intermingled with the fibers of the internal medullary lamina and thereby separate the medial from the lateral thalamic masses, and because they are considered not to have specific projections to the cerebral cortex. In this classification, the intralaminar nuclear group includes the centromedian, parafascicular, paracentral, central lateral, and limitans nuclei. Certain other descriptions include several of these nuclei in the medial thalamic nuclear group.

The **nucleus centromedianus** is situated in the middle third of the thalamus and is surrounded by fibers of the internal medullary lamina, except medially where it merges without any definite boundary with the cells of the parafascicular nucleus (Figs. 11-82; 11-85). This nucleus is more prominent in subhuman primates and man than in lower mammals. Some authors divide the nucleus into different parts on the basis of its cellular components, but the significance of this is less than clear. The centromedian nucleus is not believed to send direct fiber connections to the cerebral cortex, even though physiologic studies show a profound functional relationship between this nucleus and the cer-

ebral cortex; it does, however, project to the caudate nucleus and the putamen. Afferent fibers to the nucleus appear to come from many sources, including ascending fibers from the reticular formation of the brain stem, perhaps from the spinothalamic paths and the trigeminal system, and from the cerebellum, as well as descending fibers from the cerebral cortex and globus pallidus.

The **nucleus parafascicularis** is a prominent collection of neurons located medial to the posterior part of the nucleus centromedianus and ventral to the caudal portion of the nucleus medialis dorsalis (Fig. 11-83). The fasciculus retroflexus or habenulopeduncular tract crosses the medial part of this nucleus, but the two structures are not thought to be functionally related. The **paracentral nucleus** consists of scattered cells located along the internal medullary lamina, anterior to the nucleus centromedianus. The **nucleus centralis lateralis** is found within the internal medullary lamina behind the paracentral nucleus and lateral to the nucleus medialis dorsalis. The **nucleus limitans** is a band of neurons found between the supragenulate nucleus and the nucleus medialis dorsalis. The anatomic connections of these smaller intralaminar nuclei also have not, as yet, been determined with satisfaction.

**LATERAL NUCLEI.** The lateral group of thalamic nuclei in this description includes the dorsolateral region of the thalamus, which extends rostrocaudally from a site somewhat behind the anterior limit of the thalamus to its extreme posterior pole. This thalamic region contains the nucleus lateralis dorsalis, the nucleus lateralis posterior, and the greatly expanded pulvinar.

The **nucleus lateralis dorsalis** and the **nucleus lateralis posterior** lie in the dorsolateral thalamus, lateral to the internal medullary lamina, with the nucleus lateralis dorsalis anterior to the nucleus lateralis posterior (Fig. 11-83). There is good evidence to indicate that the nucleus lateralis dorsalis projects to the inferior parietal and posterior cingulate regions of the cerebral cortex, while the nucleus lateralis posterior projects largely to the parietal cortex, behind the postcentral gyrus. Both nuclei also receive corticothalamic fibers as well as interconnecting fibers from other adjacent thalamic nuclei.

The **pulvinar** is a large nuclear mass that

forms nearly the entire caudal end of the thalamus (Fig. 11-83). It overlies the geniculate bodies as well as the dorsolateral aspect of the mesencephalic tectum. A phylogenetically recent structure, it is best developed in the subhuman primate and in the human brain, although it can also be seen in the thalami of carnivores and other mammals. The pulvinar is usually divided into lateral, medial, and inferior nuclei on the basis of topography and cytoarchitecture. The *lateral nucleus* comprises the lateral part of the pulvinar and it lies dorsal to the lateral geniculate body. The *medial nucleus* is larger and nearly twice the volume of the lateral nucleus, while the *inferior nucleus* is also relatively large but lies more ventrally between the medial and lateral geniculate bodies. The pulvinar probably receives most of its afferent fibers from other thalamic nuclei such as the medial and lateral geniculate bodies, the nucleus lateralis posterior, and possibly even the nearby intralaminar nuclei. The pulvinar projects widely to the cerebral cortex of the parietal, occipital, and temporal lobes.

**VENTRAL NUCLEI.** The ventral thalamic nuclear mass is most frequently divided into three nuclei: the nucleus ventralis anterior, the nucleus ventralis lateralis, and the nucleus ventralis posterior. The large and important nucleus ventralis posterior is subdivided further into the nucleus ventralis posteromedialis (VPM) and the nucleus ventralis posterolateralis (VPL).

The **nucleus ventralis anterior** is the most rostral part of the ventral nuclear group; it is located lateral to the anterior nuclear group (Fig. 11-83). It is bounded medially by the internal medullary lamina (which separates it from the anterior nuclei) and ventrolaterally by the reticular nucleus. Rostrocaudally, it extends from nearly the anterior end of the thalamus to only the midregion level of the anterior nuclei, where it is then bounded behind by the nucleus ventralis posterior. The nucleus ventralis anterior receives afferent fibers from the globus pallidus by way of the thalamic fasciculus. Additionally, this nucleus has connections with the intralaminar and midline thalamic nuclei and it receives other afferent fibers from the reticular formation and from the substantia nigra of the mesencephalon. Although there are conflicting views with respect to the thalamocortical projections from the nucleus

ventralis anterior, many authors have offered evidence to suggest projections to areas 6 and 4, the frontal lobes, and the insular lobe. In turn, corticothalamic fibers to the nucleus have also been described.

The **nucleus ventralis lateralis** is located behind the nucleus ventralis anterior and gradually replaces it without a sharp line of demarcation. Laterally it is bounded by the nucleus reticularis and the external medullary lamina; medially are found the internal medullary lamina and the intralaminar nuclei (Fig. 11-83). Behind the nucleus ventralis lateralis are located the parts of the nucleus ventralis posterior, i.e., the large nucleus ventralis posterolateralis and the smaller nucleus ventralis posteromedialis. Some authors have described various subdivisions of the nucleus ventralis lateralis based on cytoarchitecture, but these will not be detailed here. The nucleus ventralis lateralis has interconnections with midline and intralaminar nuclei in the thalamus. Afferent fibers to the nucleus ventralis lateralis are derived from the contralateral dentate nucleus of the cerebellum and course through the superior cerebellar peduncle. Other ascending fibers are derived from the red nucleus, while descending fibers reach the nucleus ventralis lateralis from the globus pallidus as well as from cortical areas 4 and 6. Efferent thalamocortical fibers project to motor and premotor areas 4 and 6 in a somatotopic manner.

The **nucleus ventralis posterior** is the largest of the nuclear masses in the ventral part of the thalamus. It commences somewhat rostral and lateral to the nucleus centromedianus and continues back to the pulvinar as the posterior part of the ventral thalamus (Fig. 11-83). Its lateral boundary is the external medullary lamina and the nucleus reticularis. The nucleus ventralis posterior serves as an important sensory relay nucleus, and as such is subdivided into the smaller ventral posteromedial nucleus and the large ventral posterolateral nucleus.

The **nucleus ventralis posteromedialis** (VPM) lies adjacent to the lateral and ventral aspects of the rounded nucleus centromedianus and therefore was formerly called the semilunar or arcuate nucleus (Figs. 11-83; 11-85). It is located medial to the nucleus ventralis posterolateralis and ventral to the nucleus lateralis posterior. On the basis of cytoarchitectural and physiologic data, a

small-celled or parvocellular region is now considered to be the thalamic relay nucleus for secondary neurons of the taste pathway; these neurons probably originate in the nucleus solitarius of the lower brain stem or from a site in the pons called the pontine taste region. The remainder of VPM contains larger neurons and serves as the thalamic relay nucleus for both crossed and uncrossed secondary sensory trigeminal system fibers, which transmit somatosensory information from the face and head; this information is then received in the nucleus somatotopically. Efferent thalamocortical fibers from VPM course in the posterior limb of the internal capsule and project somatotopically to the head and face sensory receiving areas of the postcentral gyrus in the cerebral cortex.

The *nucleus ventralis posterolateralis* (VPL) forms the large lateral part of the nucleus ventralis posterior. It is situated rostral to the pulvinar and immediately lateral to the nucleus ventralis posteromedialis; it consists of large, sparsely distributed, easily stained neurons. It is to the VPL thalamic nucleus that the fibers of the medial lemniscus and the spinothalamic tracts project, but it should be stated that the terminations of the fibers from these tracts account for only a small percentage of the synapses in VPL. Other afferent fibers in VPL are derived from the mesencephalic reticular formation, the midline and reticular nuclei of the thalamus, the medial telencephalic fasciculus (medial forebrain bundle), as well as many corticofugal fibers from the somatosensory cortex. Thus, according to Brodal (1981), it would be an oversimplification to consider the VPL as purely a relay nucleus for impulses from the dorsal column nuclei and spinothalamic tracts. The pattern by which fibers transmitting impulses of the various modalities terminate on VPL neurons is a question that has been complicated over the past 25 years by the use of various anesthetics and by an attempt to compare findings from different species. Efferent fibers from the nucleus ventralis posterolateralis project to the sensory receiving areas of the postcentral gyrus, as do those from the nucleus ventralis posteromedialis.

**RETICULAR NUCLEUS OF THE THALAMUS.** The reticular nucleus of the thalamus is a thin, curved band of large nerve cells, situated

between the external medullary lamina and the internal capsule (Fig. 11-83). It forms a cellular shell that envelopes much of the anterior two-thirds of the thalamus on its dorsolateral, lateral, and ventrolateral aspects. Although the reticular nucleus is frequently described as part of the dorsal thalamus, it is a derivative of the ventral thalamus (subthalamus) and its substance is continuous ventrally with the zona incerta. Many afferent fibers reach the nerve cells of the reticular nucleus from the cerebral cortex in an apparently topographic manner, but the efferent projection from the reticular nucleus is not to the cortex. Instead its neurons send fibers caudally to the reticular formation of the mesencephalon and to other thalamic nuclei. The precise manner by which this nucleus alters cortical activity is obscure, yet its electrical stimulation causes marked changes in the pattern of the electroencephalogram.

### *The Metathalamus*

The metathalamus is the region of the diencephalon composed principally of the medial and lateral geniculate bodies, which serve as important relay nuclei in the auditory and visual pathways. Some authors classify the geniculate bodies as structures in the posterior part of the dorsal thalamus, along with the pulvinar; however, because they lie at the interface between the midbrain and the diencephalon in a region that also contains a certain amount of pretectal tissue, the term metathalamus will be retained in this description.

**MEDIAL GENICULATE BODY.** The medial geniculate body is a small oval tubercle that lies, on each side, under the pulvinar of the dorsal thalamus and on the lateral aspect of the superior colliculus (Figs. 11-64; 11-65; 11-83). It is, however, connected to the inferior colliculus by a prominent bundle of fibers called the **brachium of the inferior colliculus**. Internally, the nerve cells that form the **medial geniculate nucleus** serve to relay impulses along the central auditory pathway from fibers ascending in the lateral lemniscus and the brachium of the inferior colliculus to the auditory receiving areas of the temporal lobe. The efferent medial geniculocortical projection reaches the cerebral cor-

tex by way of the auditory radiation in the posterior portion of the internal capsule.

Careful cytoarchitectural studies of the medial geniculate complex have demonstrated the probability that morphologic and functional subdivisions exist within the medial geniculate nucleus. Analyses of Golgi-impregnated material (in the cat) led Morest (1964, 1965) to subdivide the medial geniculate nucleus into medial, dorsal, and ventral parts, all of which are nonlaminated except for a portion of the ventral part. Cells in the laminated region of the ventral part serve as the principal auditory relay station, receiving input from the central nucleus of the inferior colliculus and projecting di-

rectly to the primary auditory cortex in a tonotopic manner. The nonlaminated regions of the medial geniculate nucleus receive input from multiple structures, including the cerebellum, and impulses of other sensory modalities in addition to the auditory sense. These regions also appear to project more diffusely to the temporal cortex, but much detail still needs to be learned about the role of the medial geniculate complex in hearing.

**LATERAL GENICULATE BODY.** The lateral geniculate body is an oval elevation on the lateral aspect of the posterior end of the thalamus (Figs. 11-64; 11-65; 11-83; 11-85; 11-86). It is physically connected to the superior

**Fig. 11-86.** A dissection of the right cerebral hemisphere, viewed from below, exposing the lateral geniculate body and the spiraled, fan-shaped optic radiation coursing in the posterior limb of the internal capsule to the visual cortex in the occipital lobe. (Courtesy of Dr. Charles F. Bridgman, who drew it from a dissection made by the late Professor A. T. Rasmussen.)

colliculus by the **brachium of the superior colliculus**, which is formed by primary optic nerve fibers that do not terminate in the lateral geniculate body but, instead, project to the pretectal region and superior colliculus. These optic fibers function importantly through the tectospinal tracts and the nuclei innervating the extraocular muscles in the visual motor reflexes. Most of the fibers in the human optic tract, however, do project to the lateral geniculate body, where they synapse with neurons in the lateral geniculate nucleus.

The **lateral geniculate nucleus** actually consists of a small ventral nucleus and a somewhat larger dorsal nucleus. In the human brain, the ventral nucleus is a small cluster of cells that is often called the **pregeniculate nucleus**. Its neurons are oriented toward the zona incerta of the ventral thalamus, and in lower mammals, the ventral nucleus projects not only to the zona incerta but to the pretectal region and superior colliculus and to other structures. Although the pregeniculate nucleus has been shown to receive retinal fibers in several species, its cells do not project to the cerebral cortex.

The dorsal or **principal lateral geniculate nucleus** is a laminated structure that in the human brain consists of six easily recognized curved layers of cells oriented in a dome-shaped mound, with its blunted crest directed dorsolaterally and its shallow hilus directed ventromedially (Fig. 11-87). The lay-

ers of neurons are separated by bands of optic nerve fibers and the cellular laminae are numbered from 1 to 6, beginning at the hilus and continuing dorsally toward the crest of the geniculate body. The first two layers consist of large cells and sometimes are referred to as the magnocellular layers, while layers 3 to 6 are composed of smaller neurons. Nerve fibers that cross the optic chiasma (i.e. from the contralateral retina) terminate in layers 1, 4, and 6, while the optic nerve fibers that do not cross (and are derived from the ipsilateral retina) synapse in layers 2, 3, and 5. An enormous amount of research has been reported on the retinotopic organization of the lateral geniculate nucleus, and one morphologic feature, the **synaptic glomerulus**, emphasizes the fact that lateral geniculate neurons contain dendritic synaptic pools with terminals from interneurons and corticofugal fibers, in addition to those from primary afferent ganglion cells of the retina. The lateral geniculate nucleus projects to the striate area (Brodmann's area 17) on the occipital cortex by way of the optic radiation (Fig. 11-86). The lateral geniculocortical fibers pass to the cerebral cortex in the retrolenticular, or most posterior, portion of the internal capsule.

### The Epithalamus

The epithalamus is situated on the dorso-medial aspect of the caudal diencephalon and includes the **habenular trigone** and the underlying habenular nuclei and commissure, the **pineal body**, and the **posterior commissure**.

**HABENULAR TRIGONE.** When viewed from above, the habenular trigone is a small, depressed triangular area located in front of the superior colliculus on each side of the epithalamus. Beneath its surface are found the **medial and lateral habenular nuclei**, which form a spherical mass of cells on each side. The habenular nuclei are functionally related to the olfactory pathways, and between the nuclei of the right and left sides, rostral to the stalk of the pineal body, courses the **habenular commissure**. As might be expected, the habenulae are relatively smaller in man than in macrosmotic animals. Many afferent fibers reach the habenular nuclei by way of the **stria medullaris thalami** and some of these cross in the habenular commissure to the opposite side.

**Fig. 11-87.** Photomicrograph of the lateral geniculate nucleus showing the six cellular laminae, numbered from the hilus to the dorsal surface of the nucleus. Cresyl violet, 10  $\times$ . (From E. C. Crosby, T. Humphrey, and E. W. Lauer, *Correlative Anatomy of the Nervous System*, Macmillan Publishing Co., New York, 1962.)

Afferent connections are derived from the amygdala by way of the stria terminalis, and from the hippocampus, the septal nuclei and preoptic region, and the anterior thalamic nuclei. The principal efferent pathway from the habenular nuclei is the **habenulopeduncular tract** (also called the fasciculus retroflexus). This pathway arises from both medial and lateral nuclei, courses through the caudal part of the nucleus medialis dorsalis of the thalamus, through the red nucleus, and finally terminates in the interpeduncular nucleus. Other fibers terminate in the mesencephalic reticular formation.

**PINEAL BODY.** The pineal body (or epiphysis) is a small, conical, gland-like structure that lies in a depression at the midline between the two superior colliculi. It is placed beneath the splenium of the corpus callosum, from which it is separated by the tela choroidea of the third ventricle. It measures about 6 to 8 mm in length and about 4 mm in width; it is attached by a stalk that is composed of a superior lamina contiguous with the habenular commissure and an inferior lamina adjacent to the posterior commissure (Fig. 11-88).

Surrounded by pia mater from which it receives its blood supply, the pineal body consists of cords of epithelioid cells called **pinealocytes**, which contain the usual organelles as well as large numbers of microtubules. Additionally, the organ contains **interstitial cells** that possess large numbers of fine filaments and resemble astrocytic neuroglial cells. Although the precise function of the pineal body is still not clear, it does appear to be capable of suppressing the secretion of gonadotrophin from the pituitary gland. Precocious puberty has been observed in children in whom the pineal body has lesions or has been destroyed. The pineal body contains melatonin and large quantities of serotonin, and it has been suggested that the organ plays an active role in the regulation of certain diurnal rhythms.

**POSTERIOR COMMISSURE.** The posterior commissure is a rounded bundle of white nerve fibers that crosses the midline at a site just rostral to the superior colliculi and immediately dorsal to the cerebral aqueduct, where, in fact, the aqueduct becomes continuous with the third ventricle (Figs. 11-81; 11-82). The fibers are derived from several sources, including clusters of neurons within and around the posterior commissure called the interstitial and dorsal nuclei of the poste-

**Fig. 11-88.** The thalami, third ventricle, and pineal body exposed from above. The trunk and splenium of the corpus callosum, most of the septum pellucidum, the body of the fornix, the tela choroidea with its contained plexuses, and the epithelial roof of the third ventricle have all been removed.

rior commissure and from the nucleus of Darkschewitsch, the interstitial nucleus of Cajal, the pretectal nuclei, and the superior colliculi. The precise functions served by the various fibers that cross in the posterior commissure are not well understood.

### The Subthalamus

The subthalamus (or ventral thalamus) lies ventral to the hypothalamic sulcus and is a transitional zone between the dorsal thalamus and the tegmentum of the mid-brain. It is continuous structurally with the mesencephalon and both the red nucleus and the substantia nigra are prolonged upward into the most caudal subthalamic region. The subthalamus lies medial to the internal capsule, which separates it from the globus pallidus, and it is located caudal and lateral to the hypothalamus. In addition to the red nucleus and substantia nigra, the subthalamus contains the subthalamic nucleus, the zona incerta, the nuclei of the tegmental fields of Forel,<sup>1</sup> and the entopeduncular nucleus (nucleus of the ansa lenticularis). The fiber bundles coursing with

<sup>1</sup>August H. Forel (1848–1931): A Swiss neurologist (Zurich).

the subthalamus include the ansa lenticularis, the fibers of the tegmental field (field H of Forel), the fasciculus thalamicus (field H<sub>1</sub> of Forel), the fasciculus lenticularis (field H<sub>2</sub> of Forel), and the fasciculus subthalamicus, as well as others.

**SUBTHALAMIC NUCLEUS.** The subthalamic nucleus is an oval, biconvex mass of gray substance seen only in mammals and located in the more caudal part of the subthalamus. It is positioned along the medial aspect of the internal capsule, which separates the nucleus from the globus pallidus. In the caudal diencephalon, it lies over the dorsal surface of the crus cerebri and dorsolateral to the substantia nigra. The subthalamic nucleus receives fibers from the lateral segment of the globus pallidus and sends fibers through the internal capsule, by way of the **subthalamic fasciculus**, to the medial segment of the globus pallidus. Additionally, other connections of the subthalamic nucleus with the putamen, the caudate nucleus, the mesencephalic tegmentum, and the substantia nigra have been described but not ascertained. Lesions of this nucleus result in contralateral hemiballismic movements, which seem to be alleviated if secondary lesions are placed in the medial globus pallidus.

**ZONA INSERTA.** The zona inserta is a thin layer of diffuse gray substance that is located immediately ventral to the dorsal thalamus and extends nearly the entire rostrocaudal length of the diencephalon. It is continuous laterally with the reticular thalamic nucleus and caudally with the mesencephalic reticular formation. It lies just above the fasciculus lenticularis and below the thalamic fasciculus (field H<sub>1</sub> of Forel). The zona inserta probably receives nerve fibers from the globus pallidus and the precentral region of the cerebral cortex, and some evidence exists to indicate that efferent fibers are distributed to the mesencephalic tegmentum. The precise function of this region and the manner in which it might influence the great motor pathways, however, are still unknown.

**FIELDS OF FOREL.** Rostral to the red nucleus is a dense mass of longitudinally running fibers known as the **tegmental field (field H) of Forel**. The medial fibers are composed of dentato-, rubro-, and reticulothalamic connections. They continue rostrally as the **thalamic fasciculus** (field H<sub>1</sub> of Forel), which enters the medial part of the external medullary lamina and ends in the nucleus

ventralis lateralis of the thalamus. The lateral fibers of the tegmental field come from field H<sub>2</sub> of Forel, which is located rostrally and laterally. It is composed of fibers from the globus pallidus in the **ansa lenticularis** and **fasciculus lenticularis** that curve around the medial edge of the internal capsule on the way to the red nucleus and reticular substance.

### *The Hypothalamus*

The hypothalamus is located ventral to the thalamus and it forms the floor and the lower lateral walls of the third ventricle (Fig. 11-82). Strictly speaking, the hypothalamus is considered to extend from the mammillary bodies caudally to the optic chiasma rostrally (Fig. 11-89). The preoptic region, which lies dorsal to and in front of the optic chiasma, is a telencephalic derivative; however, it is usually included in descriptions of the hypothalamus because the functions of the two regions are so closely interrelated. The hypothalamus, consisting of slightly more than 4 gm of tissue, occupies only a small part of the entire brain, and yet it functions diversely and importantly in the regulation of many autonomic and behavioral reactions. Through its connections with the hypophysis, the hypothalamus exerts an enormous influence over the endocrine system and thereby over the general metabolic functions of many organs. The hypothalamus assists in the regulation of body temperature, in feeding, drinking, and mating behavior, in functions relating to biologic rhythms such as the reproductive cycles, and probably even in the onset of sleep. Its role in the maturation of behavior associated with the genders is actively being investigated. Additionally, this part of the diencephalon participates importantly in the behavioral translation of emotional feelings such as fear and rage, and within the hypothalamus are found high concentrations of many neurally active substances such as noradrenaline, serotonin, dopamine, and acetylcholinesterase. As might be expected, the nuclear patterns and the many connections of the hypothalamus with other regions of the central nervous system are complex. For descriptive purposes, the hypothalamus can be divided *longitudinally* into lateral and medial zones that extend throughout its length, or *transversely* into preoptic, supraoptic, tuberal (or infundibu-

**Fig. 11-89.** The inferior surface of the brain, showing the hypophysis and infundibulum and the tuber cinereum and mammillary bodies of the hypothalamus. The cranial nerves are shown in yellow.

lar), and posterior (or mammillary body) regions.

Although the precise boundaries of these hypothalamic regions are quite arbitrarily defined, certain longitudinally oriented nerve fiber bundles, such as the fornix and the mamillothalamic tract, have been conveniently used to separate the lateral and medial hypothalamic zones. In this account, however, each of the four transverse regions listed above will be described, and these descriptions include both medial and more lateral structures.

#### PREOPTIC REGION

The preoptic region occupies a part of the basal forebrain in front of the optic chiasma (Fig. 11-90). Although it is derived from the telencephalon rostral to the hypothalamus, the preoptic region is usually described with

the hypothalamus because it functions importantly in the regulation of certain autonomic mechanisms, frequently in concert with the hypothalamus. Even though the optic chiasma serves as an arbitrary boundary between the preoptic region and the anterior hypothalamus, the gray matter of the **medial preoptic zone** extends forward from the anterior hypothalamus, with no sharp line of demarcation. The **preoptic periventricular nucleus** is located adjacent to the wall of the preoptic recess of the third ventricle and the **medial preoptic nucleus** is found ventral to the anterior commissure.

In the **lateral preoptic zone** are located the **lateral preoptic nucleus** and fascicles of fibers belonging to the **medial forebrain bundle**. Both preoptic zones are interconnected with olfactory centers, the hypothalamus, and the anterior and medial thalamic nuclei. The preoptic region is importantly related to

temperature regulation, probably by initiating mechanisms that increase the loss of body heat, such as sweating, vasodilation, and in certain animals, panting. Acute lesions in this region frequently result in a rapid rise in body temperature.

### SUPRAOPTIC REGION

The supraoptic region of the hypothalamus lies dorsal to the optic chiasma, ventral to the fornix, and caudal to the preoptic region. It extends behind the anterior commissure and contains the paraventricular nucleus, suprachiasmatic nucleus, and the anterior hypothalamic nucleus medially, and the supraoptic nucleus and the rostral part of the lateral hypothalamic nucleus more laterally (Fig. 11-90).

The **paraventricular nucleus** is a pyramidally shaped group of nerve cells located immediately ventral to the fornix. It is adjacent to the **periventricular nucleus**, which forms a thin vertical column of cells located just deep to the ependyma of the third ventricle and extends nearly to the base of the brain. The **suprachiasmatic nucleus** is a small collection of neurons located directly dorsal to the optic chiasma, and the more diffusely cellular **anterior hypothalamic nucleus** lies adjacent to the paraventricular nucleus in the more medial part of the anterior hypothalamus and blends rostrally with the medial preoptic zone.

Overlying the optic tract near its divergence posterolaterally from the optic chiasma is the well defined **supraoptic nucleus**. It consists of deeply staining, moderately large cells with a rich capillary bed, and the nucleus is easily differentiated from the less compact gray substance of the **lateral hypothalamic nucleus**, which merges forward imperceptibly with the lateral preoptic zone.

The cells of the paraventricular and supraoptic nuclei send fibers to the posterior lobe of the hypophysis by way of the infundibular stalk to form the paraventriculohypophysial and supraopticohypophysial tracts (Fig. 11-91). The cells in these nuclei synthesize neurosecretory material that passes down the axons to the infundibulum and the posterior lobe. It is believed that these neurosecretions are precursors of the important hormones vasopressin (the antidiuretic hormone) and oxytocin (the uterine-contracting and milk-releasing hormone),

which are secreted by the posterior lobe. The suprachiasmatic nucleus receives a projection of fibers directly from the optic nerve and retina; these fibers are thought to be an important link relating the light-dark diurnal cycles to the secretion of hormones and the physiologic circadian rhythms. The more diffuse anterior hypothalamic regions, both medially and laterally, participate with the preoptic zones in temperature regulation, as well as with other hypothalamic regions in the secretion of releasing factors and inhibiting factors that influence the production of anterior lobe hormones from the hypophysis.

### TUBERAL (OR INFUNDIBULAR) REGION

The tuberal or infundibular region occupies the intermediate portion of the hypothalamus between the more anteriorly located supraoptic region and the caudally placed mammillary region. It is marked on its ventral surface by the tuber cinereum, the median eminence, and the infundibulum, the latter interconnecting the brain and the hypophysis (Fig. 11-89). The **tuber cinereum** is an elevated mound of gray substance situated between the optic chiasma anteriorly and the mammillary bodies posteriorly. Laterally, the tuber cinereum is bounded by the optic tracts and the cerebral peduncles, and in the midline just behind the optic chiasma, a hollow conical process, the **infundibulum**, projects ventrally and rostrally to end in the posterior lobe of the **hypophysis cerebri**, or pituitary gland. At the floor of the third ventricle is located a slightly raised region, the **median eminence**, which encircles the site at which the infundibulum becomes the stalk of the pituitary gland.

Surrounding the lateral walls of the third ventricle in the tuberal region are collections of small neurons that are oriented vertically; these collectively constitute the **periventricular nucleus**. More ventrally, in the region of the infundibulum, these cells become more compact, and in transverse or coronal sections they may be identified as an arch-shaped group of neurons, the **arcuate** (or infundibular) **nucleus**, which forms the floor of the third ventricle (Fig. 11-90). Occupying most of the medial part of the tuberal region and located between the lateral wall of the third ventricle and the fornix are the ventromedial and dorsomedial nuclei of the hypothalamus. The **ventromedial nucleus** con-

**Fig. 11-90.** Schematic diagram of the more medially located hypothalamic nuclei as seen from a midsagittal view of the diencephalon. (From M. B. Carpenter, *Human Neuroanatomy*, 7th ed., Williams and Wilkins, Baltimore, 1976.)

sists of an oval mass of densely packed cells that is more conspicuous in lower mammals than in humans, where it is less well defined. Overlying the ventromedial nucleus is the somewhat less distinct **dorsomedial nucleus** (Fig. 11-90), and dorsal to this latter nucleus is an even more diffuse band of cells and fibers that is frequently referred to as the dorsal hypothalamic nucleus (region or area).

Located lateral to the fornix in the tuberal region of the hypothalamus is the **lateral hypothalamic region**. This is continuous both rostrally and caudally with the lateral parts of the hypothalamus at the suprachiasmatic and mammillary levels, which similarly consist of a loose mixture of both fibers and cells. Also found in the lateral hypothalamic region between the level of the infundibulum and the more caudal plane of the mammillary nuclei are several small columns of cells called the **tuberomammillary nucleus** and the **lateral tuberal nuclei**. The latter form small enlargements that are visi-

ble on the ventral surface of the tuber cinereum. These nuclei are believed to send fibers to the infundibular stalk.

The intake of food and fluids is markedly altered by lesions involving various sites in the hypothalamus. Additionally, stimulation of certain hypothalamic regions as well as other CNS sites produces striking changes in overt behavior. Bilateral lesions in the ventromedial nuclei result in an excessive appetite for food, and the resulting **hyperphagia** soon leads to obesity. Animals with such lesions also display varying degrees of savage behavior and inappropriate rage reactions to relatively nonthreatening stimuli. Lesions placed laterally at approximately the same hypothalamic levels tend to result in a loss of appetite, and the resulting **aphagia** leads to emaciation. Destruction of the infundibulum or the more rostrally located supraoptic nucleus, which gives rise to the hypothalamohypophyseal tract concerned with the production of vasopressin, results in an ex-

cessive intake of fluids and a greatly increased urinary output, a condition known as *diabetes insipidus*. Electrical stimulation of anterior hypothalamic sites induces drinking behavior, and increases in blood pressure and violent attack behavior can be observed by stimulation of the region around the fornix.

The role of the supraoptic and paraventricular nuclei in the production of hormones by the posterior lobe of the pituitary gland has already been mentioned; however, there is considerable evidence that the hypothalamus also plays an important role in the secretion of anterior lobe hypophyseal hormones. Although there are no direct neural connections between the hypothalamus and the anterior pituitary, it is believed that these influences result from humoral agents, and that neurosecretions are transported along a fine network of vascular sinusoids that drain from the hypothalamus to the anterior lobe (Fig. 11-91). Overlapping zones in the hypothalamic region between the preoptic level and the level of the mammillary

bodies are thought to be importantly involved in the production of releasing factors (probably peptides) that influence the secretion of adrenocorticotrophic, thyrotrophic, and somatotrophic hormones, the follicle-stimulating hormone, the luteinizing hormone, as well as the prolactin-inhibiting factor.

#### POSTERIOR (OR MAMMILLARY) REGION

Behind the tuberal region is found the posterior part of the hypothalamus, which includes the posterior hypothalamic nucleus and the mammillary complex. The **posterior hypothalamic nucleus** (or area) is a moderately extensive zone that receives fibers from the medial forebrain bundle, the fornix, and the periventricular system, and it merges on its dorsal aspect with the midline nuclei of the thalamus. Caudally, it extends over the mammillary body to blend with the tegmentum of the midbrain.

Projecting prominently on each side of the ventral surface of the posterior hypothala-

**FIG. 11-91.** Diagrammatic representation of the hypothalamo-hypophyseal neural and vascular connections. Note that the paraventricular and supraopticohypophyseal neural pathways carry neurosecretions directly from the hypothalamus to the posterior lobe of the pituitary gland. In contrast, the tuberoinfundibular tract carries neurosecretions to the infundibulum and these are then transported from the infundibulum to the anterior lobe of the pituitary gland by the sinusoids of the hypophyseal portal system of veins. (From M. B. Carpenter, *Human Neuroanatomy*, 7th ed., Williams and Wilkins, Baltimore, 1976.)

mus near the midline are the **mammillary bodies** (Figs. 11-82; 11-89; 11-90). In transverse section, this mammillary region consists of the mammillary complex and scattered cells in the premammillary and supramammillary areas (Fig. 11-84). The **medial mammillary nucleus** is a large, ovoid mass of cells producing most of the protuberance of the mammillary body. The **lateral mammillary nucleus** is smaller and fits into the angle between the medial nucleus and the ventrolateral surface of the brain. The **nucleus intercalatus** is a separate group of smaller neurons that is located dorsolateral to the medial nucleus. Both medial and lateral mammillary nuclei receive fibers from the fornix of each side, the fibers decussating just above the mammillary bodies. They also receive fibers from the medial forebrain bundle, from the thalamus, and from the inferior mammillary peduncle. This latter tract arises in the mesencephalic tegmentum and terminates in the lateral mammillary nucleus, but it is rather small in the human brain. Efferent fibers from the mammillary nuclei form the mammillothalamic and mammillotegmental tracts. Initially, the two tracts course together dorsally as the **fasciculus mammillaris princeps**, but a short distance above the mammillary body they diverge. Some of the fibers form the **mammillothalamic tract** (bundle of Vicq d'Azyr<sup>1</sup>), which courses to the anterior nuclei of the thalamus; there they synapse with neurons that project to the cingulate gyrus (Fig. 11-84). Other efferent fibers in the fasciculus mammillaris princeps form the **mammillotegmental tract**, which curves caudally to course to neurons in the mesencephalic tegmentum. Some of the fibers that form this latter tract are actually descending collateral branches of the mammillothalamic fibers.

Stimulation of the posterior hypothalamus usually elicits a sympathetic response, in contrast to stimulation of anterior and pre-optic zones, from which parasympathetic responses are achieved. There is some evidence to indicate that neural mechanisms exist in the posterior hypothalamus, some of which increase the conservation of body heat and others of which increase the generation of heat. Heat conservation is accom-

plished through mechanisms that cause surface capillaries to constrict and sweating to diminish, while heat production is increased by the phenomenon of shivering and by piloerection ("goose-bumps" in man), but the exact role of the posterior hypothalamus in these temperature regulating functions has not yet been well established. Because mammillary nuclei receive large numbers of fibers from the subiculum, by way of the fornix, and from the septum and send fibers to those thalamic nuclei that project to the cingulum, it has been assumed that they participate in pathways intimately related to emotional expression. Specific lesions localized to the mammillary nuclei only, however, have not clarified their functional role in the so-called emotional circuit.

### Third Ventricle

The third ventricle is a narrow, vertical median cleft between the thalami of the two hemispheres (Figs. 11-81; 11-88). It is lined by ependyma and filled with spinal fluid. Rostrally, it communicates with the two lateral ventricles by means of an opening on each side called the **interventricular foramen**. Caudally, the third ventricle communicates with the fourth ventricle through the **cerebral aqueduct**. The third ventricle is limited by a roof, a floor, anterior and posterior boundaries, and a pair of lateral walls.

**ROOF.** The roof of the third ventricle is formed by a thin layer of ependyma that stretches between the upper edges of the lateral walls of the cavity and is continuous with the ependymal lining of the ventricle (Fig. 11-92). The outer surface of this ependymal roof is covered by a fold of pia mater called the **tela choroidea of the third ventricle**. From the inner ventricular surface of the ependymal roof can be seen two delicate vascular folds that are invaginated into the ventricle, one projecting downward on each side of the midline. These vascular processes carry with them the invaginated ependymal layer and form the **choroid plexuses of the third ventricle**.

**FLOOR.** The floor of the third ventricle is composed of structures that constitute the hypothalamus, and its anterior end slopes ventrally over the optic chiasma to form the **supraoptic recess**. Behind the optic chiasma the ventricular floor is prolonged downward into the infundibulum as the funnel-shaped

<sup>1</sup>Felix Vicq d'Azyr (1748-1794): A French anatomist (Paris).

FIG. 11-92. Coronal section of the third and lateral ventricles (diagrammatic).

**infundibular recess.** Posteriorly, the floor is formed by the posterior perforated substance and by the tegmenta of the cerebral peduncles.

**ANTERIOR BOUNDARY.** The anterior boundary of the third ventricle is formed inferiorly by the **lamina terminalis**, a thin layer of gray substance that stretches from the upper surface of the optic chiasma to the rostrum of the corpus callosum. Superiorly, the anterior boundary is formed by the columns of the fornix and by the anterior commissure. Located at the junction of the anterior boundary with the ventricular floor is the small angular diverticulum called the supraoptic recess. At the junction of the anterior boundary and the roof of the third ventricle, situated between the anterior tubercles of the thalami behind and the columns of the fornix in front, are found the **interventricular foramina**. These narrow openings, one on each side, allow the third ventricle to communicate with the two lateral ventricles.

**POSTERIOR BOUNDARY.** The posterior boundary of the third ventricle is formed by the pineal body, the posterior commissure, and the cerebral aqueduct. The **pineal recess** is a small prolongation of the third ventricle within the stalk of the pineal gland, while the **suprapineal recess**, located in front of and above the pineal body, is a small diverticulum of the epithelium that forms the ventricular roof.

**LATERAL WALLS.** Each lateral wall of the third ventricle consists of an *upper portion*, formed by the medial surface of the anterior two-thirds of the thalamus, and a *lower portion*, formed by the medial surface of the

hypothalamus and subthalamus and the upward continuation of the gray substance of the ventricular floor (Fig. 11-92). These two parts of the lateral ventricular wall are separated by a furrow called the **hypothalamic sulcus**, which extends on each side from the interventricular foramen to the cerebral aqueduct (Fig. 11-82). The lateral wall is limited above by the taenia thalami. The columns of the fornix curve ventrally in front of the interventricular foramina and then course in the lateral walls of the third ventricle, where initially they form distinct prominences, but subsequently they course more deeply in the hypothalamus and are not visible on the lateral ventricular surface. Above the hypothalamic sulci, the lateral walls of the third ventricle are interconnected across the ventricular cavity by medial extensions of gray matter that form the **interthalamic adhesion**.

## THE TELENCEPHALON

The telencephalon or "end brain" consists of the **pars optica hypothalami**, into which the anterior part of the third ventricle projects, and the two **cerebral hemispheres**, within which are contained the lateral ventricles. The pars optica hypothalami is the portion of the basal forebrain immediately rostral to the optic chiasma and it includes principally the preoptic region. This has been described with the hypothalamus because of its similarities in function. The cerebral hemispheres are large, rounded expansions of the forebrain that occupy most of

the cranial cavity. They are incompletely divided by a deep sagittal groove, the **longitudinal cerebral fissure**, but remain interconnected by the great central white commissure, the **corpus callosum**, located immediately under this fissure. The internal structures of the hemispheres merge with those of the diencephalon and further continuity with the brain stem is established through the cerebral peduncles.

### **Cerebral Hemispheres**

The two cerebral hemispheres constitute the largest part of the brain, and, when viewed together from above, they assume the form of an ovoid mass that is broader behind than in front and whose greatest transverse diameter is across the parietal lobes. Perhaps the most distinguishing feature of the external cerebral surface is the presentation of its substance in a series of convolutions called **gyri**, between which are located grooves of varying depth called **sulci** or **fissures**. This pattern is not exhibited in all mammals, however, for some animals, such as the rat and rabbit, have a smooth or *lissencephalic* cerebral surface. It is assumed that the differential growth rates of some regions of the brain over those of other regions result in the formation of the folded, or *gyrencephalic*, cerebral surface that is characteristic of the human brain and the brains of the higher mammals. Each cerebral hemisphere consists of an extensive covering of outer gray substance called the **cerebral cortex**, the underlying fascicles of **cerebral white substance** (sometimes called the *centrum semiovale*), several internally situated masses of central gray and white substance that are collectively called the **basal ganglia**, and the **lateral ventricle**.

The cerebral hemispheres present for inspection **three surfaces**—superolateral, medial, and inferior; **three poles**—frontal, temporal, and occipital; and **five lobes** or subdivisions—frontal, parietal, temporal, occipital, and insular. Additionally, a group of phylogenetically older structures is subsumed in the term **rhinencephalon** (or limbic lobe), and the subcortical **basal ganglia** include the corpus striatum, the claustrum, and the amygdaloid body. The fascicles of **white matter of the cerebral hemispheres** may be classified into three types: nerve fibers of projection, which interconnect the

cerebral cortex with subcortical centers; commissural fibers, which interconnect cortical regions across the two hemispheres; and association fibers, which interconnect different cerebral cortical regions of the same side. All of these morphologic structures encase the cavities of the **lateral ventricles**.

**LONGITUDINAL CEREBRAL FISSURE.** The longitudinal cerebral fissure is a deep cleft located in the median sagittal plane between the two cerebral hemispheres, and it contains a sickle-shaped process of dura mater called the **falx cerebri**. The rostral and caudal parts of this fissure extend from the superior to the inferior surfaces of the hemispheres and thereby completely separate them. Its middle portion, however, separates the hemispheres for only about one-half of their vertical extent, reaching down only to a large horizontally oriented sheet of white matter, the corpus callosum, which interconnects the two hemispheres across the midline.

### **SUPEROLATERAL SURFACE OF THE CEREBRUM**

The superolateral surface of each cerebral hemisphere is convex and its shape conforms to the rounded contour of the cranial vault in which it is contained (Fig. 11-93). Superomedially, this surface is sharply bounded from the medial surface of the hemisphere by the **superior border** of the cerebrum, while inferolaterally the **lateral border** forms a more rounded boundary between the superolateral and inferior cerebral surfaces. When the cerebrum is viewed from above, its blunted anterior end forms the **frontal pole**; this is in contrast to the more acutely shaped posterior end, which is called the **occipital pole**. Laterally the anterior limit of the **temporal lobe** forms the **temporal pole** of the cerebrum.

The gyri and sulci on the superolateral surface underlie the flattened parts of the frontal, parietal, occipital, and temporal bones and their disposition initially appears to present an irregular pattern. Although certain differences can be identified between any two brains, close inspection reveals a basic arrangement of the gyri and sulci, within which limited variations exist. Certain sulci form the boundaries between large subdivisions, or lobes, of the cerebrum. Two such sulci are the lateral sulcus and the central sulcus.

**Fig. 11-93.** A lateral view of the superolateral surface of the left cerebral hemisphere.

**LATERAL SULCUS.** The lateral sulcus, sometimes called the Sylvian fissure, is a well marked cleft situated on the lateral and inferior surfaces of the hemisphere, and it separates the larger superior masses of the frontal and parietal lobes from the temporal lobe (Figs. 11-93; 11-94). It is a complete fissure, isolating much of the temporal lobe, and the floor of its posterior portion is formed by the limen insulae and the insula. The lateral sulcus consists of a short **stem**, which begins on the inferior surface of the brain in a depression at the lateral angle of the anterior perforated substance. From this point, it extends between the anterior part of the temporal lobe and the orbital surface of the frontal lobe to achieve the lateral border of the hemisphere. This part of its course corresponds in direction to the posterior border of the smaller wing of the sphenoid bone. After it reaches the inferolateral aspect of the cerebrum, the lateral sulcus divides into three rami: anterior horizontal, anterior ascending, and posterior (Figs. 11-93; 11-94). The **anterior horizontal ramus** passes forward for about 2.5 cm into the inferior frontal gyrus, while the **anterior ascending ramus** extends

upward into the same convolution for about an equal distance. The **posterior ramus** is the longest of the rami (about 7 cm) and it represents the posterior continuation of the lateral sulcus. It is directed horizontally backward and upward to terminate in the inferior parietal lobule. Within the lateral sulcus course the middle cerebral artery and vein.

**CENTRAL SULCUS.** The central sulcus (also called Rolandic fissure) is an important landmark on the superolateral surface of the cerebrum because it forms the boundary between the frontal and parietal lobes and it also separates the primary somatomotor region of the cerebral cortex, located just in front of the sulcus, from the primary somatosensory region just behind it (Figs. 11-93; 11-94; 11-96). The sulcus begins on the medial surface of the hemisphere, a little behind the midpoint between the frontal and occipital poles (Fig. 11-95). It follows an oblique course downward and forward, along the lateral surface of the cerebrum, and it ends a little above the posterior ramus of the lateral sulcus and about 2.5 cm behind the ascending ramus of that sulcus. Its

**FIG. 11-94.** Lateral view of the superolateral surface of the left cerebral hemisphere. Pink, frontal lobe; blue, parietal lobe; yellow, occipital lobe; green, temporal lobe.

course forms an angle of about  $70^\circ$  with the superior border, and it has two sinuous curves, a **superior genu**, with its convexity directed posteriorly, and an **inferior genu**, with its convexity directed anteriorly; additional curves are frequently seen in different brains. The length of the central sulcus is about 9 cm if measured in a straight line, or 10 cm if measured along the curves. Its depth varies along its course from 1.0 to 2.0 cm.

This variable depth occurs because during the sixth month of prenatal development, the central sulcus appears as two sulci—a short upper and a longer lower, which are interrupted by a transversely oriented interlobar gyrus. After further development, the two sulci usually fuse and the transversely oriented gyrus is buried in the floor of the central sulcus, thus altering the sulcal depth.

**FIG. 11-95.** Medial surface of the left cerebral hemisphere with the brain stem and cerebellum removed. Pink, frontal lobe; blue, parietal lobe; yellow, occipital lobe; green, temporal lobe.

### Sulci and Gyri on the Superolateral Surface of the Frontal Lobe

The frontal lobe is the most anterior and largest of the lobes in the human cerebrum and its convex superolateral surface extends from the frontal pole to the central sulcus, the latter separating it from the parietal lobe. Usually the superolateral surface of the frontal lobe is traversed by three sulci, which divide it into four gyri. These are the *precentral*, *superior frontal*, and *inferior frontal* sulci and the *precentral*, *superior frontal*, *middle frontal*, and *inferior frontal* gyri.

**PRECENTRAL SULCUS.** The precentral sulcus courses parallel to and in front of the central sulcus, the two sulci being separated by the precentral gyrus (Figs. 11-93; 11-94; 11-96). During development and maturation, the precentral sulcus is formed from three grooves, the upper two of which usually fuse so that in the fully matured brain, this sulcus generally is seen to be divided into a superior and an inferior segment; the two segments, however, may become continuous.

**SUPERIOR FRONTAL SULCUS.** The superior frontal sulcus commences posteriorly at about the middle of the upper segment of the precentral sulcus and it courses forward in the superior part of the frontal lobe (Figs. 11-93; 11-94; 11-96). It is directed perpendicular to the precentral gyrus and nearly parallel to the superior border of the cerebrum. The superior frontal sulcus separates the superior frontal gyrus from the middle frontal gyrus and may exist as a continuous sulcus or be divided into two or more parts (over 50% of cases); it extends almost to the frontal pole. Small sulci extend from the superior frontal sulcus and project into the convolutions above and below.

**INFERIOR FRONTAL SULCUS.** The inferior frontal sulcus also courses horizontally in the frontal lobe, somewhat below and roughly parallel to the superior frontal sulcus (Figs. 11-93; 11-94; 11-96). Typically, it begins posteriorly as a furrow projecting forward from the inferior segment of the precentral sulcus. It may course as an uninterrupted sulcus forward to the lower or orbital part of the anterior frontal pole, but more frequently it is disconnected and forms two or more furrows. The inferior frontal sulcus separates the middle frontal gyrus above from the inferior frontal gyrus below.

**PRECENTRAL GYRUS.** The precentral gyrus is bounded in front by the precentral sulcus and behind by the central sulcus. It is positioned parallel to these sulci and extends obliquely across the superolateral surface of the cerebral cortex from the superior border of the hemisphere to the posterior ramus of the lateral fissure (Figs. 11-93; 11-94; 11-96). On the medial surface of the cerebral hemisphere, the precentral gyrus is continuous with the anterior part of the paracentral lobule (Fig. 11-95). The precentral gyrus and the anterior surface of the central sulcus function as the primary motor region of the cerebral cortex, in which the lower extremity is represented on the superior aspect and medial surface of the gyrus, followed by the upper extremity and hand on the superolateral surface, and the face, jaw, and tongue more inferolaterally.

**SUPERIOR FRONTAL GYRUS.** The superior frontal gyrus is situated above the superior frontal sulcus and it extends horizontally forward from the precentral sulcus to the frontal pole (Figs. 11-93; 11-94; 11-96). It is a relatively wide, somewhat uneven convolution and it is continued onto the medial surface of the hemisphere. The portion on the lateral surface is frequently incompletely subdivided into an upper and a lower part by a horizontal sulcus called the **paramedial sulcus**.

**MIDDLE FRONTAL GYRUS.** The middle frontal gyrus is a wide convolution that extends anteroinferiorly from the precentral gyrus and is bounded above by the superior frontal sulcus and below by the inferior frontal sulcus (Figs. 11-93; 11-94; 11-96). A horizontally oriented sulcus frequently divides the middle frontal gyrus into upper and lower parts. Inferolaterally, the middle frontal gyrus extends as far as the orbital surface of the frontal lobe.

**INFERIOR FRONTAL GYRUS.** The inferior frontal gyrus lies below the inferior frontal sulcus and extends forward from the lower part of the precentral gyrus (Figs. 11-93; 11-94; 11-96). Inferolaterally, it is continuous with the lateral and posterior orbital gyri on the inferior surface of the frontal lobe. Helping to form the superior wall of the lateral sulcus below the precentral gyrus, the inferior frontal gyrus becomes subdivided into three regions by the anterior horizontal and ascending rami of the lateral sulcus: the **orbital part** below the anterior horizontal

ramus, the **triangular part** between the anterior horizontal and the ascending rami, and the **opercular part** above and behind the ascending ramus (Fig. 11-94). The opercular part and a portion of the triangular part of the inferior frontal gyrus are frequently referred to as Broca's<sup>1</sup> **speech area** because they are importantly related to the motor aspects of speech behavior.

#### **Sulci and Gyri on the Superolateral Surface of the Parietal Lobe**

The parietal lobe is separated anteriorly from the frontal lobe by the central sulcus, but its boundaries below and behind are somewhat less definite. Posteriorly, its boundary with the occipital lobe commences at the superior border of the cerebrum by the parieto-occipital sulcus, and then it continues as an arbitrary line that starts at the lower lateral tip of this sulcus and is carried across the lateral surface of the hemisphere to a shallow indentation on the ventrolateral border of the brain called the **preoccipital incisure** (Fig. 11-94).

Inferiorly, the parietal lobe is bounded by the posterior ramus of the lateral sulcus and by another arbitrary line drawn from the site at which the posterior ramus turns to ascend into the parietal lobe to the point at which this line intersects the posterior boundary line. Two sulci, the **postcentral sulcus** and the **intraparietal sulcus**, subdivide the superolateral surface of the parietal lobe into the **postcentral gyrus**, the **superior parietal lobule**, and the **inferior parietal lobule**.

**POSTCENTRAL SULCUS.** The postcentral sulcus is oriented parallel to the central sulcus and lies posterior to it, and the two sulci are separated by the postcentral gyrus (Figs. 11-93; 11-94). The sulcus may be a continuous fissure, but at times it is interrupted and has two parts, a superior and an inferior sulcus. The postcentral sulcus extends downward along the superolateral surface of the parietal lobe from a site close to the longitudinal cerebral fissure above. It ends inferiorly just above the posterior ramus of the lateral sulcus at a site slightly anterior to the upward turn of that ramus. Anterior to the postcentral sulcus is located the postcentral gyrus, while posterior to it are the superior

and inferior parietal lobules, which are themselves separated by the intraparietal sulcus.

**INTRAPARIETAL SULCUS.** The intraparietal sulcus is an anteroposteriorly oriented fissure that commences at about the middle of the postcentral sulcus and extends horizontally backward toward the occipital pole (Figs. 11-93; 11-94; 11-96). It divides the posterior part of the parietal lobe into an upper portion called the superior parietal lobule and a lower part called the inferior parietal lobule. The intraparietal sulcus extends posteriorly into the occipital lobe to join the transverse occipital sulcus at nearly a right angle.

**POSTCENTRAL GYRUS.** The postcentral gyrus extends along the superolateral surface of the parietal lobe from the longitudinal cerebral fissure above to the posterior ramus of the lateral sulcus below (Figs. 11-93; 11-94; 11-96). Its oblique anteroinferior course on the hemisphere is limited in front by the central sulcus and behind by the postcentral sulcus. It lies nearly parallel to the precentral gyrus, with which it is physically connected around the lower end of the central sulcus. The postcentral gyrus serves as the primary somesthetic cortex, in which general sensory projections are represented in a characteristic somatotopic pattern. The anal, genital, foot, and leg regions are localized on the medial surface of the postcentral gyrus, followed by the thigh, trunk, neck-head, upper limb, hand, face, tongue, pharynx, and intra-abdominal regions, in that order, on the superolateral convexity of the gyrus. The territories along the gyrus that are devoted to the hand and face are disproportionately large in comparison to those for other parts of the body.

**SUPERIOR PARIETAL LOBULE.** The superior parietal lobule is located between the superomedial border of the hemisphere and the intraparietal sulcus (Figs. 11-93; 11-94; 11-96). Anteriorly, it is bounded by the superior part of the postcentral sulcus, around the upper end of which it is continuous with the postcentral gyrus. Posteriorly, the superior parietal lobule is continuous with the **parieto-occipital arcus** or gyrus, a U-shaped convolution that curves around the lateral limit of the **parieto-occipital sulcus**.

**INFERIOR PARIETAL LOBULE.** The inferior parietal lobule lies below the intraparietal sulcus and behind the lower part of the post-

<sup>1</sup>Pierre P. Broca (1824-1880): A French surgeon, neurologist, and anthropologist (Paris).

**FIG. 11-96.** The superolateral surface of the left cerebral hemisphere, viewed from above. Pink, frontal lobe; blue, parietal lobe; yellow, occipital lobe.

central sulcus (Figs. 11-93; 11-94; 11-96). It extends posteriorly as far as the arbitrary line that defines the posterior limit of the parietal lobe. The inferior parietal lobule is divided into the supramarginal gyrus, the angular gyrus, and an additional posterior convolution. The **supramarginal gyrus** arches over the upturned end of the lateral sulcus and it is continuous in front with the lower end of the postcentral gyrus and posteroinferiorly with the superior temporal gyrus. The **angular gyrus** caps the posterior end of the superior temporal sulcus, behind and below which it is continuous with the middle temporal gyrus. An additional convolution of the inferior parietal lobule often lies behind the angular gyrus and it is continuous below with the inferior temporal gyrus.

### Sulci and Gyri on the Superolateral Surface of the Occipital Lobe

The occipital lobe is small in comparison to the other cerebral lobes, and it has a pyramidal shape, with the apex of the pyramid forming the occipital pole of the hemisphere (Fig. 11-94). Its superolateral surface is limited in front by the lateral part of the parieto-occipital sulcus and by an arbitrary line from that sulcus to the preoccipital incisure. Although there is considerable variability with respect to the sulcal and gyral pattern on this convex surface of the occipital lobe, the most frequently observed sulci include the **transverse occipital sulcus**, the **lateral occipital sulcus**, and the **lunate sulcus** (Fig. 11-93). The convolutions on the superolateral surface are also quite variable, but usually the lateral sulcus divides much of the occipital lobe into the **superior** and **inferior lateral occipital gyri** (Fig. 11-93). The convolution capping the parieto-occipital sulcus, which helps to form the border between the parietal and occipital lobes, is the **parieto-occipital arcus**.

**TRANSVERSE OCCIPITAL SULCUS.** The transverse occipital sulcus is one of the most constant of the sulci on the superolateral surface of the occipital lobe. It commences at the superior border of the cerebrum, and when viewed from the side, it descends on the surface of the cerebrum a variable distance (about 2.0 cm), just behind the posterior part of the parieto-occipital sulcus (Figs. 11-93; 11-94; 11-96). When viewed from behind, the course of the sulcus appears to be more transverse because of the slope of the occipital lobe. About midway along its course, it is usually joined, at nearly a right angle, by the posterior end of the intraparietal sulcus, which as mentioned previously extends posteriorly into the occipital lobe.

**LATERAL OCCIPITAL SULCUS.** The lateral occipital sulcus, when present, is always a short sulcus that extends horizontally (anteroposteriorly) on the lateral surface of the occipital lobe, dividing it into the superior and inferior occipital gyri (Figs. 11-93; 11-94). It is usually located in front of the lunate sulcus, and its course anteriorly is perpendicular to that of the lunate sulcus.

**LUNATE SULCUS.** The lunate sulcus is a short, semilunar-shaped sulcus oriented vertically on the lateral surface of the occipital lobe, a short distance in front of the occipital

pole (Fig. 11-93). This crescentic sulcus approximately limits the striate area anteriorly on the lateral surface; it is present in about 70% of human occipital lobes. At times, the lunate sulcus is joined posteriorly by the anterior end of the calcarine sulcus.

**PARIETO-OCCIPITAL ARCUS.** The parieto-occipital arcus is a U-shaped gyrus that caps the lateral end of the parieto-occipital sulcus (Figs. 11-93; 11-94; 11-96). This small, arched convolution is usually bounded below by the occipital part of the intraparietal sulcus and behind by the superior part of the transverse occipital sulcus. The anterior limb of the gyrus is arbitrarily considered to be in the parietal lobe, and its posterior limb, in the occipital lobe because the parieto-occipital sulcus, around which the gyrus arches, forms the boundary between these two lobes.

**SUPERIOR AND INFERIOR LATERAL OCCIPITAL GYRI.** The horizontally oriented lateral occipital sulcus divides the lateral aspect of the occipital lobe into the superior and inferior occipital gyri (Fig. 11-93). These gyri lie behind the middle temporal sulcus, extend to the posterior border of the cerebrum, and vary in number and in shape. The superior lateral occipital gyri lie above the lateral occipital sulcus, while the inferior gyri lie below the sulcus.

#### **Sulci and Gyri on the Lateral Surface of the Temporal Lobe**

The temporal lobe is located below the lateral sulcus and in front of the occipital lobe; it is limited posteriorly by an arbitrary line drawn from the preoccipital incisure to the site at which the parieto-occipital sulcus crosses the superomedial margin of the cerebrum, about 5 cm in front of the occipital pole (Fig. 11-94). Its location on the cerebrum becomes apparent as early as the second fetal month, when a slight depression appears on the smooth surface of the developing cortex; the depression later deepens to form the **lateral cerebral fossa** and the **lateral sulcus**. The margins of this fossa continue to grow, forming the overlapping folds of the **opercula**, and the sulcus itself elongates in both directions to separate the temporal lobe from the frontal and parietal lobes anteriorly and superiorly. No specific cleft ever forms to separate the temporal lobe from the occipital lobe.

The lateral aspect of the temporal lobe is divided into three parallel gyri by two sulci. The names of the gyri present no confusion because they are simply called the **superior**, **middle**, and **inferior temporal gyri**. The sulcus between the superior and middle temporal gyri is the **superior temporal sulcus**, and the sulcus between the middle and inferior temporal gyri is now called the **inferior temporal sulcus**. Formerly, this latter sulcus was called the middle temporal sulcus and the term inferior temporal sulcus was reserved for the fissure located below the inferior temporal gyrus. Current terminology recognizes only two long temporal sulci on the lateral surface of the temporal lobe (the superior and inferior temporal sulci), and the sulcus below the inferior temporal gyrus (or medial to the gyrus, if it is located on the inferior surface of the lobe) is now called the **occipitotemporal sulcus**.

**SUPERIOR TEMPORAL SULCUS.** The superior temporal sulcus courses below the superior temporal gyrus and follows an oblique course upward and backward across the temporal lobe. It extends from a site near the temporal pole into the parietal lobe, where the angular gyrus caps its uppermost posterior end (Figs. 11-93; 11-94). It separates the superior from the inferior temporal gyri and its course is initially parallel to the lateral sulcus and then parallel to the posterior ramus of the lateral sulcus. The superior temporal sulcus is most frequently a continuous fissure, but at times it forms a discontinuous line that is separated into two or three sections.

**INFERIOR TEMPORAL SULCUS.** The inferior temporal sulcus separates the middle temporal gyrus from the inferior temporal gyrus (Figs. 11-93; 11-94). It follows the same general direction as the superior temporal sulcus, but it is rarely a continuous fissure. Most frequently it consists of two to six fragmented segments (the average is four), which usually appear as a disconnected line that commences at a site near the inferolateral border of the temporal lobe and may extend into the inferior parietal lobule. Often, however, it terminates in the posterior part of the temporal lobe before reaching the parietal lobe.

**SUPERIOR TEMPORAL GYRUS.** The superior temporal gyrus is bounded by the posterior ramus of the lateral sulcus and by the superior temporal sulcus (Figs. 11-93; 11-94). It

extends from the temporal pole to the anterior part of the inferior parietal lobule, where it is continuous with parts of the supramarginal and angular gyri. The anterosuperior bank of this gyrus forms the **temporal operculum** and helps to overlap the **insula**, which lies in the floor of the lateral sulcus. This opercular surface of the superior temporal gyrus is marked by three or four **transverse temporal sulci** which define several short, obliquely oriented convolutions called the **transverse temporal gyri** (of Heschl<sup>1</sup>). These serve as the primary auditory receiving areas of the cerebral cortex.

**MIDDLE TEMPORAL GYRUS.** The middle temporal gyrus is located between the superior and inferior temporal sulci, and it courses in a somewhat convoluted pattern backward and upward, roughly parallel to the superior temporal gyrus (Figs. 11-93; 11-94). It commences at the temporal pole and it ends in the inferior parietal lobule, where it is continuous with part of the angular gyrus and with the posterior convolution of that lobule.

**INFERIOR TEMPORAL GYRUS.** The inferior temporal gyrus courses backward from the temporal pole below the inferior temporal sulcus, and it forms the inferolateral border of the temporal lobe (Figs. 11-93; 11-94). Posteriorly, it becomes continuous with the inferior lateral occipital gyri of the occipital

lobe. The inferior temporal gyrus also extends onto the inferior or ventral surface of the cerebral hemisphere and is limited there by another anteroposteriorly coursing fissure called the **occipitotemporal sulcus**. The portion of the inferior temporal gyrus that extends beyond the inferolateral border of the temporal lobe and is located on the inferior temporal surface lateral to the occipitotemporal sulcus is designated the **lateral occipitotemporal gyrus**.

#### Insula or Central Lobe

The insula lies hidden in the depths of the lateral sulcus on the lateral aspect of the cerebrum, and it can be seen only if the lips of the sulcus are bent backward or are cut away (Fig. 11-97). The cortical gyri that overlap this central or insular lobe of the cerebral cortex are derived from the overgrowth of the frontal, parietal, and temporal lobes. These gyri are separated by the anterior (horizontal), anterior ascending, and posterior rami of the lateral sulcus, and they are called the frontal, frontoparietal, and temporal opercula.

**OPERCULA OF THE INSULA.** The **frontal operculum** actually includes two parts, an **orbital part**, which lies below the anterior (horizontal) ramus of the lateral sulcus and consists of the **pars orbicularis** of the inferior frontal gyrus, and a **frontal part**, which lies between the anterior (horizontal) and anterior ascending rami and consists of the

<sup>1</sup>Richard L. Heschl (1824-1881): An Austrian pathologist and anatomist (Vienna).

Fig. 11-97. The insula of the left side, exposed by removing the opercula.

**pars triangularis** of the inferior frontal gyrus (Fig. 11-94). The **frontoparietal operculum** is bounded by the anterior ascending ramus of the lateral sulcus and the upturned end of the posterior ramus, and it consists of the **pars opercularis** of the inferior frontal gyrus, plus the lower parts of the precentral and postcentral gyri, and the anterior part of the supramarginal gyrus (Fig. 11-94). The **temporal operculum** is the largest of the opercula of the insula and, located below the posterior ramus of the lateral sulcus, it consists of the superior temporal gyrus and the transverse temporal gyri.

**SULCI AND GYRI OF THE INSULA.** The insula is encircled and separated from the opercula by a deep furrow called the **circular sulcus of the insula** (Fig. 11-97). This is sometimes called the limiting sulcus of Reil.<sup>1</sup> When the opercula are removed, the insula is seen as a pyramidal eminence, the apex of which is called the **limen insulae**. This apex is found on the basal surface of the cerebrum and it points toward the anterior perforated substance. From it the sulci and gyri of the insula are directed superiorly in a radial manner. The deepest sulcus, called the **central sulcus of the insula**, divides the insula into a large anterior and a smaller posterior part. The anterior part is subdivided by several shallow **sulci breves** (short sulci) into three to five **gyri breves insulae**, while the more elongated posterior part is formed by a single, long gyrus, the **gyrus longus insulae**, which is usually divided by a slight furrow that bifurcates its upper end (Fig. 11-97). The cortical gray substance of the insula is continuous with the gray substance in the cortex of the surrounding opercula, and the deep surface of the insula overlies the putamen of the neostriatum. Stimulation of the insular cortex in the human brain results in visceral sensations and autonomic responses.

#### MEDIAL SURFACE OF THE CEREBRUM

The two cerebral hemispheres are apposed at the median sagittal plane and their medial surfaces are flattened, oriented vertically, and interconnected in their central regions by a large commissure of white matter called the corpus callosum (Figs. 11-95;

11-98). Immediately surrounding much of the corpus callosum on the medial cerebral surface are the sulcus of the corpus callosum, the cingulate gyrus, and the cingulate sulcus. Beyond these are the outer sulci and gyri that mark the medial aspect of the frontal, parietal, and occipital lobes. Below are located the convolutions and sulci on the inferomedial surface of the temporal lobe, but these are described with the inferior surface of the cerebrum.

**CORPUS CALLOSUM.** The sectioned corpus callosum presents the appearance of a broad-arched band; it forms one of the most distinguishing features on the medial surface of the cerebrum (Fig. 11-98). If the two cerebral hemispheres are observed when they are still interconnected, the corpus callosum can be located in the floor of the longitudinal cerebral fissure. It consists of fascicles of myelinated nerve fibers whose main function appears to be the transmission of information between the neocortical portions of the two hemispheres during the learning process. Below the anterior and middle parts of the corpus callosum, however, the cerebral hemispheres are also joined by three other tracts—the hippocampal commissure, the anterior commissure, and the crossed fibers of the optic chiasma.

When visualized on the medial surface of one cerebral hemisphere in a split brain, sectioned along the median sagittal plane, the corpus callosum is seen to consist of three divisions: (1) a curved anterior end called the **genu**, which gradually tapers into a thinner portion called the **rostrum**, the latter being continued downward and backward in front of the anterior commissure to join the **lamina terminalis**; (2) a thick, rounded, posterior end termed the **splenium**, situated dorsal to the pineal body and the corpora quadrigemina, from which it is separated by the tela choroidea of the third ventricle; and (3) a middle portion or **trunk** of the corpus callosum, which arches dorsally between these anterior and posterior extremities (Figs. 11-98; 11-99).

Central to the curvature of the anterior half of the corpus callosum can be seen the laminae of the **septum pellucidum**. These are two thin plates of gray and white matter that extend on each side between the corpus callosum and another curved, flattened fascicle of white matter, the **fornix** (Figs. 11-98; 11-99).

<sup>1</sup>Johann C. Reil (1759–1813): A German physician, neurologist, and histologist.

**FIG. 11-98.** The medial surface of the left cerebral hemisphere in a brain that has been sectioned in the midsagittal plane. The brain stem and cerebellum have been removed by an oblique section through the thalamus to expose the inferomedial surface of the temporal lobe and the inferior surface of the occipital lobe. (After Sobotta.)

**SULCUS OF THE CORPUS CALLOSUM.** The sulcus of the corpus callosum (callosal sulcus) is a slit-like fissure that separates this commissure of white matter from the overlying cerebral cortical substance (Fig. 11-98). It commences below or ventral to the rostrum of the corpus callosum and then encircles the convexity of the callosal trunk; finally, it curves around the splenium, where it then becomes continuous with the hippocampal sulcus. Immediately surrounding the corpus callosum and separated from it by the callosal sulcus is the cingulate gyrus.

**CINGULATE GYRUS.** The cingulate gyrus is an arched convolution that lies in its entirety adjacent to the corpus callosum and is separated from it by the sulcus of the corpus callosum (Fig. 11-98). It begins below the rostrum, curves around in front of the genu, extends along the dorsal surface of the trunk, and then turns downward behind the splenium of the corpus callosum, where it is connected by the narrow **isthmus of the cingulate gyrus** to the parahippocampal gyrus. The cingulate gyrus is separated from the **medial frontal gyrus** by the cingulate sul-

cus and from the **precuneus** by the more variable **subparietal** (or **suprasplenial**) **sulcus**. The cingulate gyrus has many reciprocal interconnections with the anterior thalamic nuclei, and frequently it is considered to be a part of the "limbic system."

**CINGULATE SULCUS.** Visible on the medial surface of the cerebral hemisphere is the cingulate sulcus, a fissure that begins below the anterior end of the corpus callosum, from which it is separated by the cingulate gyrus (Fig. 11-98). This sulcus courses forward and then upward and backward, paralleling the rostrum, genu, and the trunk of the corpus callosum, as well as the callosal sulcus. Posteriorly, the cingulate sulcus ascends a short distance behind the upper end of the central sulcus to the superomedial border of the hemisphere, where it separates the precuneus on the medial surface of the parietal lobe from the paracentral lobule. This upturned posterior end of the cingulate sulcus is sometimes called the **marginal portion of the cingulate sulcus**. Another branch, the **paracentral sulcus**, usually curves dorsally from the cingulate sulcus, at some distance

rostral to the marginal portion, and marks the boundary between the medial frontal gyrus and the paracentral lobule (Fig. 11-98).

The variable **subparietal sulcus** is located more posteriorly, but follows the same direction as the cingulate sulcus beyond the site at which the marginal portion curves dorsally. This sulcus sometimes is directly continuous with the cingulate sulcus, but frequently it is not, and it incompletely separates the more posterior part of the cingulate gyrus from the precuneus (Fig. 11-98).

### Medial Surface of the Frontal Lobe

On its medial surface, the frontal lobe stretches from the frontal pole anteriorly to a vertically oriented arbitrary line posteriorly. This line extends downward from the superomedial border of the cerebrum, at the site at which the central sulcus curves onto the medial surface, through the **paracentral lobule** and cingulate gyrus to the sulcus of the corpus callosum, near the midpoint of the callosal trunk. The rostral halves of the paracentral lobule and cingulate gyrus and the medial frontal gyrus form most of the medial surface of the frontal lobe (Figs. 11-95; 11-98).

The **medial frontal gyrus** is clearly separated inferiorly from the portion of the cingulate gyrus located within the frontal lobe by the cingulate sulcus, while the posterior end of the medial frontal gyrus and the anterior half of the paracentral lobule are separated by an ascending branch of the cingulate sulcus that is called the **paracentral sulcus** (Fig. 11-98). The convolution found between the paracentral and central sulci, i.e., much of the anterior half of the paracentral lobule, actually is the medial extension of the precentral gyrus from the lateral cerebral surface, and it functions as the somatomotor region for much of the lower extremity.

Anteriorly the medial frontal and cingulate gyri curve nearly 180° backward around the genu of the corpus callosum, thereby becoming oriented posteriorly under the rostrum of the corpus callosum. The medial frontal gyrus then becomes continuous with the **subcallosal** (or **parolfactory**) **area**, being incompletely separated from it by the rather shallow **anterior parolfactory sulcus** (Fig. 11-99). Behind the subcallosal area, between the **lamina terminalis** and the posterior

**Fig. 11-99.** The medial surface of the anterior part of the left cerebral hemisphere, showing the subcallosal and parolfactory regions. (From E. C. Crosby, T. Humphrey, and E. W. Lauer, *Correlative Anatomy of the Nervous System*, Macmillan Publishing Co., New York, 1962.)

**parolfactory sulcus**, is the **paraterminal gyrus**, which forms the anteroinferior continuation of the **indusium griseum**, a thin lamina of gray matter that overlies the superior surface of the corpus callosum.

### Medial Surface of the Parietal Lobe

The anterior boundary of the parietal lobe on the medial surface of the cerebrum is formed by the central sulcus, from which then is continued an imaginary line extending from the termination of this sulcus ventrally to the sulcus of the corpus callosum (Fig. 11-95). The posterior boundary is formed by the prominent parieto-occipital

sulcus. Between these boundaries are located the posterior portions of both the paracentral lobule and the cingulate gyrus, and the entire **precuneus** (Figs. 11-95; 11-98). The marginal branch of the cingulate sulcus separates the paracentral lobule from the precuneus, and the **parieto-occipital sulcus** courses between the precuneus and the anterior limit of the medial surface of the occipital lobe. The cingulate sulcus and its caudal continuation, the subparietal sulcus, limit both the paracentral lobule and the precuneus ventrally from the cingulate gyrus (Fig. 11-98).

The posterior part of the paracentral lobule consists of the extension of the postcentral gyrus from the lateral surface onto the medial cerebral surface, and it functions as the primary somatosensory receiving region for much of the lower limb. The precuneus, located on the dorsomedial part of the hemisphere, represents the medial extension from the superolateral surface of the superior parietal lobule.

#### Medial Surface of the Occipital Lobe

The medial surface of the occipital lobe is marked by the parieto-occipital and calcarine sulci, which form the boundaries of a wedge-shaped lobule called the **cuneus**. Extending backward into the occipital lobe from the inferior surface of the temporal lobe is the posterior end of the **collateral sulcus**. Between the calcarine sulcus and the collateral sulcus is located the **lingual gyrus**, which is the caudal continuation of the parahippocampal gyrus (Figs. 11-95; 11-98).

**PARIETO-OCCIPITAL SULCUS.** The parieto-occipital sulcus commences on the convex superolateral aspect of the cerebral hemisphere, about 5 cm in front of the occipital pole. After coursing superiorly for slightly more than 1 cm, it continues around the superomedial border of the cerebrum and, as a deep cleft, it forms the rostral boundary of the occipital lobe on the medial surface (Fig. 11-95). Its course is directed downward and slightly forward, where it then joins the calcarine sulcus at an angle of about 45°. Beyond this junction the sulcus, which continues forward, is called the anterior part of the calcarine sulcus. The parieto-occipital sulcus separates the precuneus from the cuneus, and in the human brain, it almost always joins the calcarine sulcus, thereby

forming a Y-shaped configuration (Fig. 11-98). If the junction between these two sulci is opened widely, a submerged transitional gyrus, the **anterior cuneolingual gyrus**, which was buried by the overgrowth of the surrounding gyri, can be exposed.

**CALCARINE SULCUS.** The calcarine sulcus begins slightly above the occipital pole, usually on the medial surface but at times on the lateral surface of the occipital lobe. Along the medial aspect of the cerebrum it courses forward between the cuneus and the lingual gyrus, and it is frequently characterized by a dorsal curve, in front of which it is joined by the descending parieto-occipital sulcus (Figs. 11-95; 11-98). It continues anteriorly below the isthmus of the cingulate gyrus and splenium of the corpus callosum, where, for a short distance, it forms the upper boundary of the parahippocampal gyrus before terminating.

The portion of the calcarine sulcus in front of the junction with the parieto-occipital sulcus is frequently called the **anterior part of the calcarine sulcus** (Fig. 11-98), and it gives rise to a prominence called the **calcar avis**, which is visible on the medial wall of the posterior horn of the lateral ventricle. The primary visual receiving area, the **striate cortex**, is located on the upper and lower banks, as well as in the depth of the **posterior part** of the calcarine sulcus (i.e., the portion of the sulcus behind its junction with the parieto-occipital sulcus). Another submerged gyrus, the **posterior cuneolingual gyrus**, can be seen crossing the floor of the sulcus near the occipital pole. This can be exposed by separating the lips of the posterior part of the calcarine sulcus.

#### INFERIOR SURFACE OF THE CEREBRUM

The inferior or ventral surface of the cerebral hemisphere consists anteriorly of the orbital surface of the frontal lobe and, more posteriorly, of the inferior surface of the temporal and occipital lobes. The stem of the lateral sulcus commences on the inferior surface of the cerebrum, near the anterior perforated substance, and forms a natural division between the orbital surface of the frontal lobe and the inferior surface of the temporal lobe. The inferior surface of the occipital lobe and that of the more posterior part of the temporal lobe rest on the tentorium of the cerebellum, while the anterior

part of the inferior temporal surface lies on the floor of the middle cranial fossa.

### Inferior or Orbital Surface of the Frontal Lobe

The inferior or orbital surface of the frontal lobe is concave and rests on the orbital plate of the frontal bone laterally, on the cribriform plate of the ethmoid bone medially, and on the lesser wing of the sphenoid bone posteriorly. Together these bony structures form the **anterior cranial fossa** on the inner aspect of the neurocranium. Most medially, the inferior surface of the frontal lobe presents a straight and deep anteroposteriorly oriented sulcus called the **olfactory sulcus** (Fig. 11-100), within which lies the olfactory bulb and the olfactory tract. Medial to this sulcus is found the **gyrus rectus**, a narrow, straight gyrus that occupies the region along the ventromedial margin of the frontal lobe. The gyrus rectus is continuous anteriorly with the medial frontal gyrus and posteriorly it meets the parolfactory area (Figs. 11-98; 11-100).

Lateral to the olfactory sulcus, the orbital surface contains the somewhat variable **orbital sulci**. These often assume an H-shape, the lateral and medial sides of which course parallel to the gyrus rectus. Thus, the **lateral**, **medial**, and **transverse orbital sulci** divide this region into the lateral, anterior, posterior, and medial orbital gyri (Fig. 11-100).

The **lateral orbital gyrus** is continuous around the inferolateral margin of the cerebral cortex with the inferior frontal gyrus.

The **anterior orbital gyrus** is located in front of the transverse orbital sulcus and represents the orbital surface continuation of the middle frontal gyrus around the frontal pole of the cerebrum. The **posterior orbital gyrus** is located behind the transverse orbital sulcus and it extends backward nearly to the pyramidal apex of the insula, called the **limen insula**. The **medial orbital gyrus** lies medial to the medial orbital sulcus and becomes continuous with the superior frontal gyrus around the frontal pole of the cerebrum (Fig. 11-100).

### Inferomedial Surface of the Temporal Lobe

The inferomedial surface of the temporal lobe has a concave shape and is continuous posteriorly with the tentorial surface of the occipital lobe. It is traversed by the **collateral** and **occipitotemporal sulci**, which course posteroanteriorly, as well as by the **rhinal sulcus**. These sulci divide the region into **medial** and **lateral occipitotemporal gyri** and the **parahippocampal gyrus**, the anteromedial extremity of which curves back to form a hook called the **uncus** (Figs. 11-95; 11-98).

**COLLATERAL SULCUS.** The collateral sulcus is a relatively long fissure that commences posteriorly near the occipital pole and courses rostrally along the tentorial surface of the occipital lobe and the inferomedial surface of the temporal lobe, where it may be continuous with the rhinal sulcus but more frequently is not (Figs. 11-95; 11-98). Caudally, it separates the lingual gyrus from the medial occipitotemporal gyrus (formerly called the fusiform gyrus), and more anteriorly it courses between the parahippocampal gyrus, which is the rostral continuation of the lingual gyrus, and the medial occipitotemporal gyrus. The **rhinal sulcus**, which is directed anteriorly in the same line as the collateral sulcus, separates the terminal part of the parahippocampal gyrus and its anteromedial continuation, the **uncus**, which is archeopallial in origin, from the remainder of the temporal lobe more laterally located.

**OCCIPITOTEMPORAL SULCUS.** The occipitotemporal sulcus courses parallel but lateral to the collateral sulcus. Its origin, like that of the collateral sulcus, is in the occipital lobe but it commences more anterior to the occipital pole than does the lateral sulcus (Figs. 11-95; 11-98). The occipitotemporal sulcus is

Fig. 11-100. Orbital surface of left frontal lobe.

usually a discontinuous fissure of three or more segments, and throughout its extent, it separates the medial occipitotemporal gyrus from the lateral occipitotemporal gyrus. In some older descriptions, this sulcus is called the inferior temporal sulcus because the lateral occipitotemporal gyrus is continuous around the inferolateral margin of the temporal lobe with the inferior temporal gyrus.

**PARAHIPPOCAMPAL GYRUS.** The parahippocampal gyrus (formerly called the hippocampal gyrus) is located on the upper aspect of the inferomedial surface of the temporal lobe, where it arches forward toward the temporal pole from the isthmus of the cingulate gyrus, with which it is continuous (Figs. 11-95; 11-98). Posteriorly, the parahippocampal gyrus is continued into the occipital lobe as the lingual gyrus, while antero-medially its extension forms the uncus, a rounded convolution that has a hooked shape because it is reflected posteriorly and medially upon itself. Separating the parahippocampal gyrus from the medial occipitotemporal gyrus are the rhinal and collateral sulci. Above and posteriorly, the parahippocampal gyrus is bounded by the anterior part of the calcarine sulcus, while internally it is bounded by the hippocampal sulcus, which separates the parahippocampal gyrus from the dentate gyrus.

**MEDIAL OCCIPITOTEMPORAL GYRUS.** The medial occipitotemporal gyrus (formerly called the fusiform gyrus) is a long, postero-anteriorly oriented convolution that lies on the tentorial or basal surface of the cerebrum and separates the parahippocampal and lingual gyri from the lateral occipitotemporal gyrus (Figs. 11-95; 11-98). It is bounded by the collateral and rhinal sulci on its medial side and by the occipitotemporal sulcus laterally, and it extends from nearly the occipital pole to the temporal pole, where it merges with the anterior ends of the three temporal gyri from the lateral surface of the cerebrum.

**LATERAL OCCIPITOTEMPORAL GYRUS.** The lateral occipitotemporal gyrus lies parallel to the medial occipitotemporal gyrus, and although anteriorly it reaches as far as the temporal pole, it does not extend posteriorly into the occipital lobe nearly as far as does the medial occipitotemporal gyrus (Figs. 11-95; 11-98). It is separated medially from the medial occipitotemporal gyrus by the occipitotemporal sulcus. Laterally it forms

the inferolateral margin of the cerebral hemisphere and it is continuous around this border with the inferior temporal gyrus.

### Inferior Surface of the Occipital Lobe

The inferior surface of the occipital lobe overlies the arched crescentic fold of dura mater, called the tentorium cerebelli. Because the tentorium covers the cerebellum, this surface is sometimes referred to as the tentorial surface of the occipital lobe. By accommodating the superior surface of the cerebellum, its shape is somewhat concave and it extends backward all the way to the occipital pole from the temporal lobe, beyond an arbitrary line drawn between the occipital incisure and the isthmus of the cingulate gyrus. Marking the inferior surface of the occipital lobe are the posterior extensions of the collateral and occipitotemporal sulci, which were described above. The gyri are also continuous with those of the temporal lobe across the arbitrary temporo-occipital boundary; they include the posterior part of the parahippocampal gyrus, called the **lingual gyrus**, and the posterior segments of the medial and lateral occipitotemporal gyri (Fig. 11-98).

### THE RHINENCEPHALON

The term rhinencephalon is derived from two Greek words, *rhis* (rhin), meaning nose, and *enkephalos*, meaning brain. It refers to the olfactory brain and, in agreement with Brodal (1981), it is used strictly here to incorporate only the olfactory bulb and those regions that receive nerve fibers from the olfactory bulb. This more classical use of the term avoids some of the confusion in the literature that has arisen during the last several decades and focuses on the structures that are principally related to the afferent pathways for the sense of smell in the microsmotic infrahuman primate and human brain. In certain lower vertebrates, the rhinencephalon is large, and in these macrosmotic mammals much of the pallium or cortex is occupied by olfactory structures. In the subhuman primate and human brain, however, the rhinencephalon is relegated to more or less hidden regions on the medial and inferior surfaces of the hemispheres due to the enormous development of the neocortex.

In essence, the rhinencephalon consists of structures derived from the primitive olfactory and piriform lobes (Fig. 11-19) and includes the associated prepiriform and periamygdaloid cortical regions, or **paleocortex**. In this description the following structures will be considered as comprising the rhinencephalon: the olfactory bulb and tracts, including the medial, intermediate, and lateral olfactory striae; the anterior olfactory nucleus; the olfactory trigone; the anterior perforated substance (or olfactory tubercle) and diagonal band; the prepiriform, periamygdaloid, and entorhinal cortical regions of the piriform lobe; as well as the corticomедial nuclei of the amygdaloid complex.

### Olfactory Bulb

The olfactory bulb is a flat, ovoid mass of gray substance that rests on the lateral border of the cribriform plate of the ethmoid bone. Its anterior and inferior surfaces receive the olfactory nerve fibers, called **fila olfactoria**. These pass upward through the cribriform plate from the specialized olfactory epithelium, which contains the neurosensory olfactory receptor cells located in

the superior part of the nasal cavity. The smooth superior surface of the olfactory bulb underlies the rostral part of the olfactory sulcus, a fissure that courses between the gyrus rectus and the medial orbital gyrus on the orbital surface of the frontal lobe (Fig. 11-89). Because the olfactory bulb develops in the embryo around an ependymal cell-lined cavity that extends anteriorly and ventrally from the lateral ventricle, its central core in the adult still contains some ependymal cells that mark the site of the primitive olfactory ventricle.

The olfactory bulb is the primary relay station for olfactory impulses generated in the olfactory receptor cell. Although the human olfactory bulb does not have so distinct a laminar structure as that seen in certain other mammals, its organization into layers is still recognizable (Fig. 11-101). Commencing on its superficial aspect, the olfactory bulb consists of the following six laminae.

**OLFACTORY NERVE FIBER LAYER.** The olfactory nerve fiber layer is composed of axons derived from olfactory receptor bipolar neurons, whose cell bodies are located in a rather evenly distributed pattern in the olfactory epithelium of the nasal cavity. The

**FIG. 11-101.** The neuronal structure (right) and layers (left) of the olfactory bulb. (From Benninghoff and Goerttler, *Lehrbuch der Anatomie des Menschen*, 8th ed., Vol. 3, Urban and Schwarzenberg, Munich, 1967.)

fibers are collected into about 20 small nerve bundles and most of these enter the anterior and inferior aspect of the olfactory bulb to form a shallow superficial lamina.

**GLOMERULAR LAYER.** Immediately deep to the olfactory nerve fiber layer is located the glomerular layer. This consists of a band of synaptic spheres called **olfactory glomeruli**, within which the incoming olfactory receptor fibers synapse, primarily with descending dendrites from **mitral cells**. The olfactory glomeruli, which measure as much as 0.1 mm in diameter, are complex synaptic pools that contain hundreds of synaptic processes from tufted cells and multipolar neurons, called periglomerular cells, in addition to the incoming olfactory receptor fibers and dendrites from the mitral cells.

**EXTERNAL GRANULAR LAYER.** Deep to the glomerular layer is located a lamina of rounded cells that forms the external granular layer. These cells are small and multipolar and are considered periglomerular cells because their processes participate in the formation of the glomeruli.

**MOLECULAR LAYER.** Deep to the external granular layer and separating it from the mitral cell layer is a rather wide lamina of nerve cell processes called the molecular layer. Many of these processes are dendrites from mitral cells and they course superficially toward the synaptic glomeruli, but others come from granule cells and tufted cells that also participate in the glomerular synaptic pools. A few scattered nerve cell bodies are also seen in the molecular layer.

**MITRAL CELL LAYER.** The mitral cell layer is a thin lamina consisting of a single row of sparsely placed mitral cell bodies that have a pyramidal shape. These are the largest neurons in the olfactory bulb and they send their dendrites toward the surface to the olfactory glomeruli and their axons inward to the core of the olfactory bulb to form many of the fibers in the olfactory tract.

**INTERNAL GRANULAR LAYER.** Deep to the mitral cell layer is the internal granular layer, which consists of rounded or stellate neuronal cell bodies whose dendritic processes extend superficially into the molecular layer, and some may even reach the olfactory glomeruli. The cells of the internal granular layer also synapse with collaterals from the mitral cells. Deep to the internal granular layer, near the central core of the olfactory bulb, are small collections of ependymal

cells that remain as vestiges of the lining of the primitive olfactory ventricle. Also at this level are the axons of the mitral and tufted cells that form the fibers of the olfactory tract (Fig. 11-101).

### Anterior Olfactory Nucleus

In its caudal part, the olfactory bulb loses its laminated structure and the cells of the internal granular layer are replaced by scattered groups of medium-sized, pyramidal-shaped neurons that extend diffusely along the olfactory tract and collectively are called the **anterior olfactory nucleus** (Fig. 11-102). The neuronal clusters of the anterior olfactory nucleus in the human brain also extend behind the olfactory tracts along the olfactory striae to the olfactory trigone, the anterior perforated substance, the parolfactory area, and laterally to the prepiriform cortex. Some fibers in the olfactory tract synapse with the cells in the anterior olfactory nucleus, and then the axons of the postsynaptic cells enter the olfactory tract to join those olfactory tract fibers that do not synapse.

### Olfactory Tract, Trigone, and Striae

**OLFACTORY TRACT.** The olfactory tract is about 20 mm long and courses backward from the olfactory bulb as a narrow white band, triangular in section, that lies below the olfactory sulcus along the inferior surface of the frontal lobe (Fig. 11-103). It consists of axons of the mitral and tufted cells of the ipsilateral olfactory bulb, other fibers from cells in the anterior olfactory nucleus, recurrent collaterals from cells in the ipsilateral olfactory bulb, and efferent axons from the opposite olfactory bulb. These latter fibers cross in the anterior commissure to synapse on neurons of the anterior olfactory nucleus, as well as on mitral cells in the contralateral olfactory bulb. Just rostral to the anterior perforated substance, the olfactory tract joins the posteroinferior surface of the frontal lobe at a triangular expansion, the olfactory trigone. The olfactory tract then diverges into three strands: medial, intermediate, and lateral olfactory striae.

**OLFACTORY TRIGONE.** The olfactory trigone is a small, smooth, triangular wedge of cortical gray matter, located on both sides of the brain just above the optic nerve; it consists of the diverging fibers of the olfactory tract

**Fig. 11-102.** The olfactory pathways. Note the synaptic connections in the anterior olfactory nucleus and diverging olfactory tract fibers that form the olfactory striae. (From C. R. Noback, *The Human Nervous System*, McGraw-Hill, New York, 1967.)

(Fig. 11-103). With its apex directed forward and its base oriented posteriorly toward the anterior perforated substance, the olfactory trigone is bounded medially and laterally by the roots of the olfactory tracts, which continue to divide to form the medial and lateral olfactory striae.

**OLFACTORY STRIAE.** As the olfactory tract diverges caudally, its fibers form the **medial** and **lateral olfactory striae** (or tracts). These initially course along the medial and lateral sides of the olfactory trigone and enclose two of its three sides. A small third fascicle of fibers, called the **intermediate olfactory stria**, is formed between the medial and lateral striae (Fig. 11-103).

**Medial Olfactory Stria.** The medial olfactory stria passes medially along the rostral border of the anterior perforated substance and is augmented by a thin layer of gray matter to form the **medial olfactory gyrus**. Near the ventromedial border of the frontal lobe, it is accompanied in its course by the diagonal band (of Broca). These superficially located fibers ascend on the medial aspect of the hemisphere, immediately in front of the paraterminal body, which separates them from the upper end of the laminae terminalis. The fibers of the diagonal band enter

the paraterminal (or subcallosal) gyrus and the medial olfactory stria becomes continuous with the parolfactory area. Beyond the olfactory trigone, the medial olfactory stria supplies fibers to the medial part of the anterior perforated substance, the parolfactory area (of Broca), and the paraterminal gyrus. Other fibers course across the anterior commissure to terminate in the opposite olfactory bulb.

**Lateral Olfactory Stria.** The lateral olfactory stria becomes the superficial layer of the olfactory cortex and forms the **lateral olfactory gyrus**. It passes immediately laterally and caudally, around the lateral border of the anterior perforated substance and toward the anteroinferior corner of the insula (the limen insula), where it bends sharply backward and medially toward the region of the uncus. The fibers of the lateral olfactory stria terminate in the lateral part of the anterior perforated substance, the prepiriform and periamygdaloid areas, the corticomедial nuclei of the amygdaloid complex, and even in portions of the entorhinal cortex.

**Intermediate Olfactory Stria.** The intermediate olfactory stria arises from the olfactory tract between the medial and lateral ol-

**FIG. 11-103.** The basal aspect of the forebrain with the optic chiasm and optic nerves reflected caudally to show the olfactory structures. (Redrawn after M. B. Carpenter, *Human Neuroanatomy*, 7th ed., Williams and Wilkins, Baltimore, 1976.)

factory striae. It passes directly posteriorly and its fibers terminate within the ipsilateral anterior perforated substance.

### Anterior Perforated Substance

The anterior perforated substance is a flat, smooth, nearly triangular area of gray matter located on the basal surface of the cerebral hemisphere, just behind the olfactory trigone and olfactory striae (Fig. 11-103); in macrosmotic mammals it is marked by a small, oval elevation, the **olfactory tubercle**. It is named for the numerous minute orifices on its basal surface that are formed by many small penetrating branches of the middle cerebral artery, which supplies the region, and many small perforations become evident after removal of the pia mater. The fibers of the intermediate olfactory stria enter the anterior perforated substance directly from the olfactory tract. Posteromedially, the anterior perforated substance is bounded by the diagonal band of Broca and the optic nerve, while posterolaterally it is limited by the lat-

eral olfactory stria, as that bundle turns medially toward the prepiriform cortex.

The anterior perforated substance consists of three well defined layers in its middle region, but its rostral and caudal parts are poorly differentiated and show only an outer non-neurocellular plexiform zone that overlies a thin layer of gray matter. In the middle region, however, deep to the **external plexiform zone**, is found an intermediate **pyramidal cell layer**, and below this lies a **polymorphic layer** of cells. Additionally, significant collections of pyramidal and granule cells, called the *islands of Calleja*,<sup>1</sup> are scattered within the anterior perforated substance; their function is unknown.

### Piriform Lobe

The piriform lobe is so named because it is pear-shaped and it retains that appearance in many macrosmotic lower mammals. From

<sup>1</sup>Camillo Calleja y Sanchez (?-1913): A Spanish anatomist (Madrid).

rostral to caudal it includes the prepiriform area and the periamygdaloid (or piriform) area (Figs. 11-104; 11-105), which occupy the upper anterior aspect of the uncus and the entorhinal area. The latter constitutes much of the parahippocampal gyrus in the human brain (area 28). Whereas the prepiriform and periamygdaloid cortical areas are characterized by three layers, the entorhinal cortex, which is much larger in the human brain than in the brains of lower mammals, is a somewhat specialized five-layered region; it probably represents a transitional form of cortical structure, somewhat simpler than the typical six-layered isocortex.

The **prepiriform area**, frequently called the lateral olfactory gyrus, is the anterior part of the piriform lobe. It consists of a thin layer of gray substance underlying the inner border of the superficial lateral olfactory stria. It is of considerable size in lower ani-

mals and is also quite evident in the fetal human brain. In the adult human brain its relative size becomes diminished and it forms only a slight elevated ridge that initially curves laterally toward the insula and then stretches caudomedially, blending imperceptibly with the periamygdaloid area in the rostral amygdaloid region. The **periamygdaloid area** is a three-layered paleocortical region that structurally is similar to, but extends behind, the prepiriform area and overlies the amygdaloid complex (Fig. 11-105). Unlike all other primary afferent cortical receiving areas, the prepiriform and periamygdaloid areas do not receive their afferent fibers as projections from the thalamus, and they do not have large numbers of stellate (or granule) cells, which are typical in the primary visual, auditory, and somesthetic cortical receiving areas.

The **entorhinal area** is the cortical region of the most posterior part of the piriform lobe in lower mammals, and in the human brain it receives its maximal development, forming a large part of the exposed surface of the rostral parahippocampal gyrus (area 28). It is limited laterally by the rhinal sulcus and is bounded medially by the hippocampal sulcus (Fig. 11-105). The entorhinal area is a five-layered cortical region that until recently was thought to not receive direct olfactory bulb fibers. It now appears that in several animal species the entorhinal area not only receives projections from the prepiriform and periamygdaloid areas, but from the olfactory bulb as well. The entorhinal region is continuous medially by way of the subicular zones with the beginning of Ammon's horn.

For many years it has been known that the prepiriform and periamygdaloid areas receive direct projections from the olfactory bulb by way of the lateral olfactory stria, and they have been considered, therefore, the primary olfactory cortex. In contrast, the entorhinal area was thought to receive only olfactory impulses through synaptic connections in the prepiriform and periamygdaloid areas, and was therefore considered a secondary olfactory cortical region. Recent research utilizing new anatomic methods on several animal species has offered evidence that certain parts of the entorhinal area receive direct olfactory bulb projections, as well as input from the known primary olfactory cortical regions.

**Fig. 11-104.** A diagrammatic representation of the sites of termination of some of the fibers in the olfactory tract. Insert diagram shows subdivisions of the amygdaloid complex: N.o.t., nucleus of the olfactory tract. Amygdaloid nuclei: M, medial; Co, cortical; C, central; B, basal; L, lateral. (From A. Brodal, *Neurological Anatomy*, 3rd ed., Oxford University Press, New York, 1981, after H. J. Lammers, in *Neurobiology of the Amygdala*, Plenum Press, New York, 1972.)

**Fig. 11-105.** A schematic drawing showing the rhinencephalic structures of the right hemisphere as seen from a medial view. Note the prepiriform, periamygdaloid, and entorhinal parts of the piriform lobe, bounded laterally by the rhinal fissure. (From O. Larsell, *Anatomy of the Nervous System*, 2nd ed., Appleton-Century Crofts, New York, 1951.)

### Amygdaloid Body

The amygdaloid body consists of a group of nuclei, located in the dorsomedial part of the rostral temporal lobe, that underlies or forms a bulge called the uncus (Fig. 11-106). The uncus is partially covered by the periamygdaloid cortex. The amygdala overlies the rostral extremity of the temporal horn of the lateral ventricle (Fig. 11-107), and it receives its name from its almond-like shape. Its nuclear masses are divisible into two major groups: the **corticomedial nuclei** and the **basolateral nuclei**. The central amygdaloid nucleus, the boundaries of which are somewhat obscure, is usually included in the corticomedial group.

The **corticomedial nuclear group** in the human amygdaloid body is positioned in the dorsomedial part of the complex because of the nature of the rotation of the temporal lobe. It includes the **anterior amygdaloid area**, the **nucleus of the lateral olfactory tract**, and the **central, medial, and cortical amygdaloid nuclei** (Fig. 11-104). The **basolateral nuclear group** consists of the **lateral amygdaloid nucleus**, the **basal amyg-**

**daloid nucleus**, and dorsomedial to the basal nucleus and indistinctly separated from the overlying cortex, the **accessory basal amygdaloid nucleus** (Fig. 11-104). As one ascends the phylogenetic scale, the portion of the amygdaloid body consisting of the basolateral nuclear group increases in size in comparison with the portion that represents the corticomedial nuclear group. This is clearly the case when the amygdala in the human brain is compared with the same structure in infraprimate mammals such as the rat and rabbit, and these differences seem to be reflected both in the nature of the neural connections and in the functions served by the two nuclear groups.

**AFFERENT FIBER CONNECTIONS OF THE AMYGDALOID NUCLEI.** The nucleus of the lateral olfactory tract and the cortical nucleus in the corticomedial group receive direct projections from the olfactory bulb by way of the lateral olfactory stria, and thus they may be considered "rhinencephalic" structures. The basolateral nuclei also receive olfactory impulses, but these are not direct olfactory bulb projections because they come, instead, through synaptic connections in the primary

**FIG. 11-106.** A schematic drawing of a brain in which the left hemisphere has been dissected to expose the amygdaloid body and the caudate and lentiform nuclei. The left lateral ventricle is shown with a solid line where the wall is intact and with an interrupted line where it has been dissected away. Note the position of the amygdala and compare with Figure 11-107. (From S. W. Ranson and S. L. Clark, *The Anatomy of the Nervous System*, 10th ed., W. B. Saunders, Philadelphia, 1959).

olfactory cortex of the piriform lobe. Additionally, the amygdaloid nuclei receive afferent fibers from several neocortical regions. The inferior temporal cortical region has been reported to project to the central and lateral amygdaloid nuclei, while orbitofrontal cortical regions have been reported to

project to both the medial and lateral parts of the amygdala in certain species.

The amygdala also receives afferent fibers by means of pathways that formerly were considered only efferent amygdaloid tracts. Thus, the **stria terminalis** contains afferent fibers coursing to both corticomедial and

**FIG. 11-107.** A diagrammatic representation of the ventricular system in the brain to illustrate the relationship of the amygdaloid body and the caudate nucleus to the lateral ventricle. (Redrawn after E. C. Crosby, T. Humphrey, and E. W. Lauer, *Correlative Anatomy of the Nervous System*, Macmillan Publishing Co., New York, 1962.)

**Fig. 11-108.** The dorsal amygdalofugal pathway. Fibers that arise in the amygdala follow the curved postcommissural course of the stria terminalis (solid line) to terminate in the bed nucleus of the stria terminalis on the same side (L. bednc. Str.T.), as well as the preoptic area (A.P.O.). Other fibers (dashed line) course in front of the anterior commissure, curve caudally, and terminate in the ventromedial nucleus of the hypothalamus (V.M.) and the ventral premammillary region (V.Pr.M.). A few fibers (dotted line) cross in the anterior commissure (C.A.) and project to the opposite amygdala. (From H. J. Lammers in *The Neurobiology of the Amygdala*, edited by B. E. Eleftheriou, Plenum Press, New York, 1972.)

basolateral nuclear groups from the preoptic and anterior hypothalamic regions and probably also from certain thalamic nuclei. Even the so-called ventral amygdalofugal pathway is known now to contain amygdalopetal fibers from preoptic and rostral hypothalamic zones. Furthermore, the amygdaloid nuclei receive input from the nucleus medialis dorsalis of the thalamus by way of the inferior thalamic peduncle and also from the raphe nuclei and the reticular formation in the brain stem.

**EFFERENT FIBER CONNECTIONS OF THE AMYGDALOID NUCLEI.** Efferent fibers emerge from the amygdaloid nuclei by way of a **dorsal amygdalofugal tract**, which contributes to the stria terminalis and for the most part is

thought to arise in the corticomedial nuclei (Fig. 11-108), and by a **ventral amygdalofugal tract**, which principally consists of efferent fibers from the basolateral nuclei (Fig. 11-109).

The stria terminalis arises from the posterior aspect of the amygdaloid nuclei and follows a curved course, along with the thalamostriate vein, in a groove that is visible on the wall of the lateral ventricle between the thalamus and the tail of the caudate nucleus. As the stria terminalis approaches the posterior aspect of the anterior commissure, many of its fibers enter groups of neurons that are collectively called the **bed nucleus of the stria terminalis**, while other postcommissural fibers

continue ventrally into the anterior hypothalamus. Other fibers in the stria terminalis course over the anterior commissure to assume a precommissural position and then curve ventrally to end in the medial preoptic region, in the anterior hypothalamus, and more caudally in the region around the ventromedial hypothalamic nucleus (Fig. 11-108).

Efferent fibers in the ventral amygdalofugal pathway are thought to arise in part from the basal and lateral amygdaloid nuclei and in part from the prepiriform cortex. They course more directly to preoptic and hypothalamic regions, as well as to the nucleus of the diagonal band and the dorsomedial nucleus of the thalamus. This ventral amygdaloid projection appears to terminate in more lateral parts of the preoptic and hypo-

thalamic regions, in contrast to the projections from the stria terminalis, which end more medially (Fig. 11-109).

The functions of the amygdaloid nuclei appear to be many and varied, and a wide range of behavioral, visceral, and endocrine alterations are observed after electrical stimulation or selective ablation. These include arrest, arousal, and orienting responses, and flight, defense, attack, feeding, and sexual behaviors. Additionally, the amygdaloid nuclei are reported to exert an influence on the secretion of hormones such as gonadotrophin, adrenocorticotrophin, thyrotrophin, and vasopressin. In many of these functions, it appears that the amygdala functions through its anatomic connections with the hypothalamus.

**FIG. 11-109.** The ventral amygdalofugal pathway. Fibers that arise in the basal and lateral amygdaloid nuclei, as well as others that arise in the piriform and periamygdaloid cortex (solid lines) project ventromedially to the preoptic (A.P.O.) and anterior hypothalamic (A.H.A.) regions. Other fibers project to the olfactory tubercle (Tub. olf.), the diagonal band of Broca (Br.), and the anterior amygdaloid area (A.A.A.). From these latter sites nerve fibers descend in the medial forebrain bundle (M.F.B.). Also note (dashed lines) the projections from the olfactory bulb to the primary olfactory cortex. (From H. J. Lammers in *The Neurobiology of the Amygdala*, edited by B. E. Eleftheriou, Plenum Press, New York, 1972.)

**Fig. 11-110.** Median sagittal section of the brain stem and diencephalon, showing the corpus callosum, septum pellucidum (not labelled), lamina terminalis, and subcallosal and parolfactory regions.

## SEPTAL REGION

The septal region includes the **septum pellucidum**, which occupies the nearly triangular and vertically-oriented interval between the fornix and the arch of the corpus callosum, and the so-called **septal area** or **septum verum** (true septum), which is located rostral to the anterior commissure and lamina terminalis. The true septum corresponds to the medially located cortical regions called the paraterminal gyrus and the subcallosal area (Figs. 11-110; 11-111).

**SEPTUM PELLUCIDUM.** The septum pellucidum lies above the anterior commissure and therefore is sometimes referred to as the supracommissural septum. On each side, it consists of a thin, vertical partition; together these partitions separate the anterior horns of the two lateral ventricles. Each of these two laminae extends backward from the rostrum and genu of the corpus callosum and is prolonged under the body of the corpus callosum to the splenium, where it terminates. Inferiorly, each vertical lamina is attached to the fornix, and the medial surfaces of the two laminae may be fused in the midline or may enclose a narrow median cavity called

the **cavum septum pellucidi**, which is sometimes referred to as the fifth ventricle but is not known to communicate with the ventricular system. The laminae are thin sheets of neural tissue composed of a layer of "gray substance," which is located medially, adjacent to the cavum, and a layer of white matter, oriented laterally toward the ventricle, over which is spread an ependymal lining.

**SEPTAL AREA.** In a median sagittal view of the brain can be seen a region, located immediately rostral to the anterior commissure and lamina terminalis, that constitutes the paraterminal gyrus or paraterminal body (Fig. 11-110). In fact, it is the rostral continuation of a thin layer of gray substance, called the **indusium griseum** (or hippocampal rudiment), that covers the superior surface of the corpus callosum. In front of the paraterminal gyrus are the subcallosal and parolfactory areas (Figs. 11-110; 11-111). The **septal area** includes the paraterminal gyrus and the adjacent parolfactory area as well as the subcallosal area, and it consists of nuclear groups that are usually divided into the **medial** and **lateral septal nuclei**. The medial septal nucleus is coextensive with the **nucleus and tract of the diagonal band**, while

**FIG. 11-111.** Schema of the rhinencephalon and hippocampal formation. Note the septum pellucidum, paraterminal gyrus, and parolfactory area.

the lateral septal nucleus occupies the region anterodorsal to the anterior commissure and is continuous with the gray lamina of the septum pellucidum. Two other nuclear groups in this region include the **bed nucleus of the stria terminalis** and the **nucleus accumbens**.

Afferent fibers to the septal nuclei are derived from several forebrain and brain stem sites. Projections that appear to be topographically organized reach the lateral septal nucleus from the subicular part of the hippocampal formation by way of the precommissural fornix. Other afferent fibers reach the septal nuclei from the amygdala, after they pass through the stria terminalis and the diagonal band. Still other fibers from the locus ceruleus, raphe nuclei, mesencephalic reticular formation, and lateral hypothalamus course to the septum via ascending catecholaminergic fibers in the medial forebrain bundle. There also may be some input to the septum from the cingulate gyrus.

Efferent projections from the septal nuclei course back to the hippocampus through the fornix. These appear to be cholinergic fibers and they arise mainly from the medial septal nucleus. A second important septal projection travels along the medial forebrain bundle to the lateral hypothalamus, the mammillary bodies, and the tegmentum of the midbrain. Other efferent septal fibers enter

the stria medullaris and pass to the habenular and interpeduncular nuclei, and still others course along the stria terminalis to the central and medial amygdaloid nuclei. As a result of these interconnections, it can readily be appreciated that the septal area is a forebrain structure that strategically interacts with many important brain stem, diencephalic, and telencephalic structures, and it is not surprising that septal lesions can influence a variety of behaviors. The so-called septal syndrome, which is observed in some animals following septal lesions, is characterized by a transient increased aggressivity and a heightened reactivity and irritability to environmental stimuli; however, many more subtle effects are also observed in these animals when they are studied in conditioning paradigms.

#### ANTERIOR (ROSTRAL) COMMISSURE

The anterior commissure is a bundle of myelinated nerve fibers that crosses the midline just rostral to the columns of the fornix (Figs. 11-102; 11-108; 11-110). Located within the upper portion of the lamina terminalis, it overlies the preoptic area and thereby helps to form the anterior wall of the third ventricle. In sagittal section it is oval, with the long diameter of the oval oriented vertically. Its constituent fiber bundles are twisted like the

**FIG. 11-112.** Coronal sections of the human forebrain at two stages of development. In A, the neopallium occupies a restricted region in the lateral surface of the hemisphere between the hippocampus and the piriform area. In B, the neopallium has expanded, thereby displacing the hippocampus onto the medial surface of the cerebrum, close to the ependymal roof of the diencephalon. (From J. Davies, *Human Developmental Anatomy*, Ronald Press, New York, 1963.)

strands of a rope, and these curve backward and laterally, forming a deep groove on the inferior aspect of the rostral part of the lentiform nucleus. Across the anterior commissure course fibers that interconnect the olfactory bulbs and anterior olfactory nuclei, the anterior perforated substance, the diagonal band and the olfactory tubercles, the amygdaloid nuclei, the prepiriform cortex, the entorhinal area, the parahippocampal gyri and neocortical portions of the cortex in the temporal lobe, and some fibers from the frontal lobe.

#### HIPPOCAMPAL FORMATION

The hippocampal formation develops along the fringe of the pallium on the lower medial aspect of the cerebral hemisphere; it commences its differentiation even before the corpus callosum is formed. During the second prenatal month, the lower part of the medial pallial wall becomes thin near the site at which the pallium attaches to the diencephalon and is reduced to a single layer of ependymal cells, into which a layer of vascular mesenchyme grows (Fig. 11-112, A). Together, the ependymal cell layer and its associated developing blood vessels invagi-

nate into the cavity of the cerebral vesicle on each side and form the **choroid plexuses** of the lateral ventricles; the line of invagination is called the **choroid fissure**.

Meanwhile, the medial pallial wall along the upper curved border of the choroid fissure begins to thicken and develop into the hippocampal formation (Fig. 11-112, B). Further growth in its ventromedial part forces an infolding to occur, thereby creating the hippocampal sulcus around which the pallium arches over itself to form the hippocampus. As the hippocampal sulcus deepens, the invaginated pallium becomes the cornu ammonis (Ammon's horn), and the adjacent innermost lip arches to form the dentate gyrus while the outer lip forms the subicular zones and the parahippocampal gyrus (Fig. 11-113). With expansion of the temporal lobe, the enlarging hippocampal formation migrates farther downward and laterally into the lateral ventricle. The collateral sulcus, the rostral part of which is called the rhinal sulcus, invaginates the inferomedial surface of the hemisphere to form the border between the parahippocampal gyrus or entorhinal area and the medial occipitotemporal gyrus. Thus, in the fully developed brain, the arched contour of

**FIG. 11-113.** Diagrammatic coronal sections of the developing hippocampal formation. In A, B, and C note the migration of the pallial regions, which eventually form the dentate gyrus (1), cornu ammonis (2), subiculum (3), and parahippocampal gyrus (4). The fully formed hippocampal formation is shown in D. (From B. Pansky and D. J. Allen, *Review of Neuroscience*, Macmillan Co., New York, 1980.)

the hippocampal formation consists of phylogenetically old cortex (archeopallium), which blends through the parahippocampal gyrus (paleopallium) with the greatly expanded neopallium. Commencing at the choroidal fissure, the three principal zones of the hippocampal formation include the **dentate gyrus**, the **cornu ammonis**, and the **subiculum**.

Efferent fibers arise from the pyramidal cells of the hippocampus to form the **fornix**, a bundle that courses forward above the choroid fissure. Anteriorly, the fibers of the fornix enter the lamina terminalis and then turn inferiorly and grow into the region of the mammillary body of the hypothalamus. At the end of about the fourth month, fibers from neurons in the neocortical areas begin to interconnect the two cerebral hemispheres by passing across the lamina terminalis, thereby commencing the formation of the **corpus callosum** (Fig. 11-114). Prolific

growth of this great commissure, however, soon results in its extension caudally beyond the lamina terminalis. This causes a separation of the upper part of the hippocampal formation, the thin rudiment of which, the **indusium griseum**, is seen in the adult brain above the corpus callosum. Additionally, this process also causes a splitting of the fornix fibers into a dorsal component, the **medial and lateral longitudinal striae**, and a ventral component, which in the adult becomes the two columns of the fornix proper (Fig. 11-115).

#### Indusium Griseum

The indusium griseum, sometimes called the supracallosal gyrus, is a thin sheet of gray matter that covers the superior surface of the corpus callosum. Laterally, it is continuous on both sides with the cortex of the cingulate gyrus. Posteriorly, over the sple-

**Fig. 11-114.** Sagittal sections of the human fetal brain, showing stages in the formation of the corpus callosum. In A there is a massing of commissural fibers from the neopallium, dorsal to the dorsal commissure in the lamina terminalis. The callosal fibers then extend caudally (B), thereby separating the fornix fibers that lie in their path into a dorsal portion and a ventral portion. (From J. Davies, *Human Developmental Anatomy*, Ronald Press, New York, 1963.)

nium of the corpus callosum, the indusium griseum consists of right and left parts, each becoming the slender **gyrus fasciolaris**, a delicate layer of gray substance that courses ventrolaterally and forward to merge with the posterior end of the dentate gyrus (Fig. 11-111). Elevated above the surface of the indusium griseum, as well as embedded

within it, are the **medial** and **lateral longitudinal striae** (of Lancisii<sup>1</sup>). These are two longitudinal bundles of fibers on each side, the medial stria lying close to the median plane and the lateral stria hidden under the cingulate gyri on the floor of the callosal sul-

<sup>1</sup>Giovanni N. Lancisi (1654-1720): An Italian physician.

**Fig. 11-115.** Two later stages in the development of the corpus callosum. From the caudal extension of the callosal fibers (A), there results a splitting of the fornix fibers into a dorsal component (the indusium griseum and the medial and lateral longitudinal striae) and a ventral component (the columns of the fornix). Some fibers in the latter pass across the midline in the dorsal commissure, which now becomes the hippocampal commissure and is displaced caudally out of the lamina terminalis by the backward extension of the corpus callosum (B). Part of the lamina terminalis becomes stretched and incorporated into the septum pellucidum. (From J. Davies, *Human Developmental Anatomy*, Ronald Press, New York, 1963.)

cus. Anteriorly, the medial and lateral longitudinal striae on each side pass over the genu of the corpus callosum and emerge as a single band that becomes continuous with the paraterminal gyrus, which is contiguous with the diagonal band (of Broca). Posteriorly, the striae join the gyrus fasciolaris.

### The Hippocampus

The hippocampus is a curved elevation, about 5 cm long, that extends forward from its position under the posterior part of the corpus callosum to the uncus, thereby occupying the entire length of the floor of the temporal (inferior) horn of the lateral ventricle (Fig. 11-116). The picturesque name of the hippocampus implies that its shape in the forebrain is similar to that of a seahorse seen in profile. Its anterior or lower extremity appears somewhat dilated, and the lateral margin of this expanded portion is crossed by three or four shallow digitations that cause it to resemble an animal's paw; therefore it is called the **pes hippocampi**. The hippocampus is formed by a specialized type of cortex, and it consists of the dentate gyrus and the cornu ammonis. It is continuous ventrally with the subiculum of the parahippocampal gyrus (Fig. 11-117).

As described above, the hippocampus is an archeocortical gyrus that is infolded upon itself, so that its ependymal cell-lined, convex, ventricular surface is its deepest layer; this layer consists of a fasciculus of myelinated fibers called the **alveus**. The axons in the alveus converge dorsomedially to form the fimbria of the fornix (fimbria hippocampi), a flat band of white fibers that lies above the dentate gyrus and immediately below the choroid fissure. In addition to serving as an efferent path to the fornix for pyramidal and other hippocampal neurons, the alveus is also a pathway for afferent fibers to the hippocampus from the medial part of the entorhinal region and the parasubiculum.

**THE SUBICULUM.** The cortical regions that are located ventral and medial to the dentate gyrus and form an extension of the parahippocampal gyrus to the cornu ammonis are collectively called the **subiculum**. More precisely, this region is described as consisting of four zones: the parasubiculum, presubiculum, subiculum, and prosubiculum. The parasubiculum is contiguous with the entorhinal cortex (area 28) laterally and the other zones follow sequentially the curvature of the parahippocampal gyrus toward the cornu ammonis (Fig. 11-117).

The archeopallial nature of the subiculum

**Fig. 11-116.** Lateral view of a temporal lobe dissection in the left cerebral hemisphere. The lateral ventricle is opened, exposing its occipital (posterior) and temporal (inferior) horns, as well as the hippocampus and fimbria.

**FIG. 11-117.** A schematic drawing of a transverse section through the parahippocampal gyrus, subiculum, cornu ammonis, and dentate gyrus, showing the subdivisions of these regions. Note the laminae of the cornu ammonis (the stratum pyramidalis is called the stratum lucidum in this figure), the hippocampal subdivisions according to Rose (H1 to H5), and the cornu ammonis fields (CA 1 to CA 4) according to Lorente de Nó. (From H. J. Lammers and H. Gastaut in *Physiologie de l' Hippocampe*, Editions du Centre National de la Recherche Scientifique, No. 107, Paris, 1962.)

is manifested by its three-layered structure, a feature that gradually develops from the adjacent five-layered entorhinal area through the parasubicular and presubicular zones. This fundamental trilaminar cortical structure, which is characteristic of the cornu ammonis and dentate gyrus as well, includes an outer **molecular**, an intermediate **pyramidal**, and a deep **polymorphic layer**. Many afferent fibers to the subiculum, cornu ammonis, and dentate gyrus arise in the entorhinal cortex. Fibers that originate in the medial part of the entorhinal cortex and the parasubiculum enter the hippocampus, close to its ven-

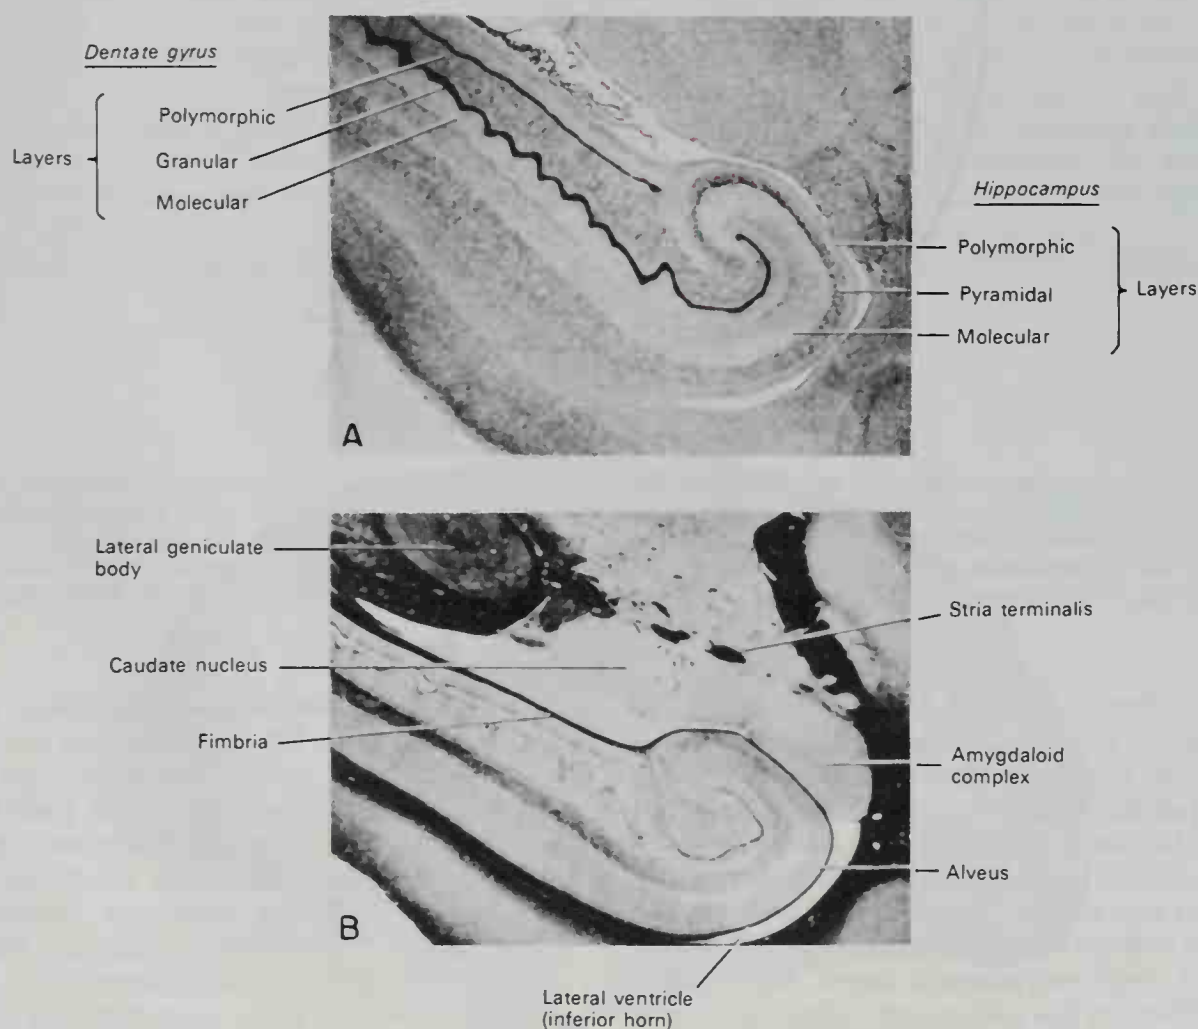

tricular surface, by way of the alveus (the **alvear path**). Fibers from the lateral portion of the entorhinal cortex course through the subicular zones along a **perforant path** that crosses the alvear path and becomes distributed widely within the cornu ammonis and dentate gyrus. These pathways constitute the so-called direct temporoammonic tracts.

**CORNU AMMONIS.** Continuous with the prosubicular zone at its open end and interlocking with the concavity of the dentate gyrus at the other, the cornu ammonis is characterized in transverse sections of the hippocampal formation by its reversed C or

comma-shaped orientation and by its tightly packed pyramidal cell layer (Fig. 11-117). Although the cornu ammonis displays the basic trilaminar archeocortical structure, commencing at the ventricular surface the following strata or sublayers are readily recognizable: (1) the *ependymal cells* of the lateral ventricle; (2) the afferent and efferent fiber bundle called the *alveus*; (3) the *stratum oriens*, containing mainly basal dendrites of pyramidal cells, but also containing nonmyelinated axon collaterals that leave to join the alveus, incoming fibers that pass in the opposite direction, irregularly-shaped polymorphic neurons, and basket cells; (4) the *stratum pyramidalis*, consisting of both large and small pyramidal cells that are oriented so that the axon, coming from the base

of each pyramidal cell or from a basal dendrite, courses through the *stratum oriens*, into the alveus, and out the fimbria of the fornix. Long axon collateral branches (the so-called Schaeffer collaterals) turn back through the pyramidal layer to the *stratum moleculare* and terminate near the base of the apical dendrites of other nearby pyramidal cells (Fig. 11-119). (5) The *stratum radiatum* consists principally of the unbranched apical dendrites of the pyramidal cells; (6) the *stratum lacunosum* has a rich plexus of pyramidal cell dendrites, various incoming axons, axon collaterals, and the cell bodies of interneurons; and (7) the *stratum moleculare* consists of fine terminal branches of apical dendrites from pyramidal cells and some incoming fibers (Fig. 11-117).

**Fig. 11-118.** Sagittal sections through the hippocampal formation in the monkey (*Macaca mulatta*). In A, the cellular layers of the hippocampus (cornu ammonis) and dentate gyrus are identified, while in B, the relationship of the alveus and fimbria to the lateral ventricle and the nearby amygdaloid body and caudate nucleus is demonstrated. (From M. B. Carpenter, *Human Neuroanatomy*, 7th ed., Williams and Wilkins, Baltimore, 1976.)

Thus, the basic trilaminar arrangement (Fig. 11-118) of the cornu ammonis might be said to be composed of the following sublayers:

- Polymorphic layer:
  - Ependymal cells
  - Alveus
  - Stratum oriens
- Pyramidal layer:
  - Stratum pyramidalis
  - Stratum radiatum
- Molecular layer:
  - Stratum lacunosum
  - Stratum moleculare

Detailed analysis of cytoarchitectural differences between the various regions of the hippocampus has led certain investigators to divide it into a series of fields. Rose (1926) designated these as **hippocampal fields H<sub>1</sub> through H<sub>5</sub>**, and Lorente de Nó (1934) divided Ammon's horn into **cornu ammonis fields CA 1 through CA 4** and pointed out their special variations in cell morphology, fiber distribution, and connections (Fig. 11-117). These two analyses are not identical, because Rose's H fields extend from the subicular transitional region through the cornu ammonis and include the dentate gyrus, while Lorente de Nó's CA fields subdivide the cornu ammonis only. Field CA 1 contains the smallest pyramidal cells and is continuous with the subiculum, whereas the largest pyramids are located in field CA 4, which lies within the curve of the dentate gyrus.

**DENTATE GYRUS.** The dentate gyrus is a narrow band of archeocortex that also con-

sists of three basic cytoarchitectonic layers: a superficial plexiform or molecular layer, a granular layer, and a deep polymorphic layer of cells (Fig. 11-118). The general configuration of the dentate gyrus resembles closely a wide-angled U, and its open concavity, which is oriented toward the fimbria, is nearly filled by the CA 4 field of the cornu ammonis. The **molecular layer** contains many interwoven neuronal processes, as well as a few polymorphic neurons, including an occasional Golgi type II cell or granule cell. The **granular layer** is composed of closely positioned spherical or ovoid granule cells and some small pyramidal cells. The dendrites of these cells are oriented toward the molecular layer, while their axons, called **mossy fibers**, course through the polymorphic layer to enter the cornu ammonis, where they synapse with the dendrites of the pyramidal cells (Fig. 11-119). The **polymorphic layer** contains some pyramidal cells and basket cells distributed within an interlacing fiber network. The dentate gyrus appears to be interposed between certain incoming afferent projections to the hippocampus and the pyramidal cell layers of the CA fields of the cornu ammonis, because afferent impulses reaching the granule cells of the dentate gyrus are clearly relayed to the hippocampal pyramids.

**HIPPOCAMPAL CONNECTIONS AND FUNCTIONS.** The hippocampus receives its principal *afferent connections* from the entorhinal cortex and subiculum along the alvear and perforant pathways of the temporo-ammonic tracts. These fibers terminate on the outer portions of the dendrites of the

**Fig. 11-119.** The diagram on the left is a schema that shows the main histologic features of the hippocampus seen in transverse section. Indicated on the right are the strata and cellular structures through the cornu ammonis (CA 2) and dentate gyrus. (From J. D. Green, *Physiol. Rev.*, 44, 1964.)

pyramidal and granule cells. Additionally, fibers from the cingulate gyrus project by way of the cingulum through synaptic connections in the subicular region, but the existence of direct projections to the hippocampus from the cingulate gyrus has been questioned. Incoming fibers from the septum reach the hippocampus along the fornix from the medial septal nucleus. These are not present in great numbers, but they seem to terminate diffusely throughout the hippocampal fields and are cholinergic in nature. Afferent fibers to the hippocampus also arise from the supramammillary region in the posterior hypothalamus, the nucleus reuniens, and the anterior nuclei of the thalamus, and from the locus ceruleus and raphe nuclei in the brain stem. Some of these latter fiber groups are adrenergic, dopaminergic, and serotonergic projections. Finally, many transhippocampal projections course through the commissure of the fornix and interconnect the two hippocampal formations.

The principal efferent pathway from the hippocampus is by way of the **fornix system** (Fig. 11-120). In addition to its afferent fibers, this thick nerve bundle contains efferent projections that achieve sites outside the hippocampal formation and commissural projections that course to the opposite hippocampus. At one time it was believed that most of the efferent fibers in the fornix represent axons of pyramidal cells. It now appears that, in addition to the pyramidal cell axons, many fibers in the fornix are derived from the subiculum and prosubiculum (Swanson and Cowan, 1977; Meibach and Siegel, 1977). On each of the two sides of the brain, fibers from these sources initially pass toward the ventricular surface to form the **alveus**. They then converge on the medial aspect of the hippocampus as the **fimbria**, a flat band of white fibers that lies above the dentate gyrus and below the lower part of the choroidal fissure. Anteriorly, the fimbria extends into the hook of the uncus, while posteriorly it ascends below the splenium of the corpus callosum, arches upward over the thalamus, and inclines toward the midline as the **crus of the fornix** (Fig. 11-120).

The two crura are connected by a lamina of transverse fibers that passes between the hippocampal formation of the two hemispheres to form the **commissure of the**

**fornix** or hippocampal commissure. This commissure presents the appearance of a thin, triangular lamina called the **psalterium** or **lyra**. At the highest part of their arch, the two crura fuse to become the **body of the fornix** (Fig. 11-120). The body of the fornix lies above the tela choroidea and the ependymal roof of the third ventricle and is attached to the undersurface of the corpus callosum and, more anteriorly, to the inferior borders of the laminae of the septum pellucidum. Laterally, the body of the fornix medially overlies the upper surface of the thalamus and the choroid fissure. Anteriorly, above the interventricular foramen, the body of the fornix divides again into the **columns** (or anterior pillars) of the fornix, which bend ventrally toward the anterior commissure and form the anterior boundary of the interventricular foramen.

About half of the fibers in the fornix descend behind the anterior commissure as the **postcommissural fornix**, while the remaining fibers descend rostral to the commissure as the **precommissural fornix**. Below the anterior commissure, a number of the fornix fibers reassemble and the bundle curves posteriorly, coursing through the gray matter in the lateral wall of the third ventricle to terminate in the medial nucleus of the mammillary body. Evidence now indicates that many of the fibers in the postcommissural fornix are derived from the subiculum and terminate in the mammillary bodies, whereas most of the fornix fibers that originate in the hippocampus proper course into the precommissural fornix and terminate in the septum.

Fig. 11-120. Diagrammatic representation of the fornix system, viewed from above and from the right side.

Along its course toward the septum and mammillary bodies, the fornix system also distributes fibers to other regions. A small group of fibers from the fimbria passes dorsal to the splenium of the corpus callosum as the medial and lateral longitudinal striae of the indusium griseum. These fibers are sometimes referred to as constituting the dorsal fornix and most of them either terminate on scattered cells in the septum pellucidum or they penetrate the corpus callosum to rejoin the main fornix bundle. The fornix also distributes fibers to the anterior thalamus. These also appear to be derived from the subiculum rather than from the hippocampal fields, to pass through the post-commissural fornix, and to project to the anterior thalamic nuclei. Projections to the lateral preoptic and anterior hypothalamic regions from the fornix course by way of the precommissural route and also represent subicular connections rather than axons from the hippocampus itself. In addition to contributing many fibers that emerge from the hippocampus along the fornix system, the subicular region also projects axons to the adjacent entorhinal cortex and to the cingulate gyrus.

The hippocampal formation at one time was considered predominantly a structure that functioned in the olfactory pathway, and this may still be true in certain macrosmotic animals. In the microsmotic human brain and in anosmotic animals such as the whale, however, the hippocampus is well developed, does not receive direct projections from the olfactory bulb, and probably functions minimally as an olfactory structure. Many alterations in physiologic and behavioral phenomena have been reported as resulting from techniques commonly utilized to stimulate or to produce lesions in and around the hippocampus. It has not been possible, however, to identify any hippocampal function that is separate and distinct from functions that are derived from hippocampal interconnections with the temporal lobe, septal, diencephalic, and brain stem structures. Because of the profound elaboration of forebrain mechanisms due to the encephalization process, observations made on lower mammals and even on subhuman primates must be carefully assessed when the functions of the human hippocampus are discussed. The role of the hip-

pocampus in altering aggressive behavior, sexual behavior, endocrine functions, attention, alertness, learning and memory have all been documented in various species. There may be some evidence that the human hippocampus functions importantly in the retention of short-term memory, but additional definitive data are required and the mechanisms involved need further exploration. The functions of the hippocampus have frequently been incorporated with those of the so-called "limbic system," a rather imprecise term popularly used to interconnect several forebrain and hypothalamic structures that are phylogenetically older, concerned with visceral functions, and appear to be related to the elaboration of emotional phenomena.

### BASAL NUCLEI

The basal nuclei, or **basal ganglia**, are large masses of gray substance deeply located in the basal regions of the cerebral hemispheres (Fig. 11-121). In part they are separated medially from the diencephalon by the internal capsule, but in front of the thalamus they form the wall of the lateral ventricle, with the internal capsule coursing through their substance. As the subcortical nuclei of the telencephalon, the basal ganglia are separated laterally and superiorly from the gray substance of the cerebral cortex by the white matter underlying the cortical laminae.

The basal ganglia include the **globus pallidus**, **caudate nucleus**, **putamen**, and **amygdaloid body** (Fig. 11-122). The latter structure has been described with the rhinencephalon and will not be considered further. The globus pallidus is frequently referred to as the **paleostriatum**, or more simply, the **pallidum**, while the caudate nucleus and putamen together constitute the **neostriatum**, commonly called the **striatum**. More inclusive is the term **corpus striatum**, which refers collectively to both the paleostriatum (globus pallidus) and the neostriatum (putamen and caudate nucleus). The corpus striatum is so named because of its striped appearance, which results from the mixture of diverging white fibers and gray substance, characteristic of its more rostral part. Reference is often made also to the **lentiform** (or **lenticular**) **nucleus**, a term that

includes the larger, more laterally located putamen and the medially placed globus pallidus. The following diagram clarifies the use of these terms:

### Caudate Nucleus

The caudate nucleus is an elongated mass of gray substance that arches over itself and, throughout its entire extent, is related closely to the wall of the lateral ventricle. Its prominent and enlarged rostral extremity, called the **head** of the caudate nucleus, is pear-shaped and occupies most of the lateral wall of the frontal (anterior) horn of the lateral ventricle. The remainder of the caudate nucleus is at first directed backward on the lateral side of the thalamus as the **body** of the caudate nucleus and is separated medially from the thalamus by the stria terminalis and thalamostriate vein. The nucleus gradually becomes drawn into a long and more slender **tail**, which initially arches downward into the temporal lobe in the roof of the temporal (inferior) horn of the lateral

ventricle, but then curves forward toward the amygdaloid body (Fig. 11-122). Around the rostral border of the internal capsule, the head of the caudate nucleus is fused with the putamen of the lentiform nucleus, while its tail terminates in close relationship to the central nucleus of the amygdala (Fig. 11-122). In most coronal sections that pass through the corpus striatum in the cerebrum, the caudate nucleus is cut twice because of this arched form.

### Lentiform Nucleus

The lentiform nucleus lies lateral to both the thalamus and the head of the caudate nucleus, and when it is sectioned horizontally, it has somewhat the shape of a biconvex lens. In totality, it is a wedge-shaped structure, shorter in rostro-caudal length than the caudate nucleus, and it does not extend as far forward (Fig. 11-122). The lentiform nucleus is located in the white substance of the cerebrum, deep to the insula; it is separated laterally from that cortical region by a lamina of white matter called the **external capsule** and by a thin layer of gray substance, the **claustrum**. Its anterior end is continuous with the lower part of the head of the caudate nucleus and with the anterior perforated substance. The lentiform nucleus is divided by a layer of white matter called the **lateral medullary lamina** into two parts: the

**Fig. 11-121.** Phantom of the corpus striatum within the cerebral hemisphere. (Courtesy of W. J. Krieg's *Functional Neuroanatomy*, 2nd ed., Blakiston Div., McGraw-Hill, New York, 1953.)

**Fig. 11-122.** The corpus striatum of the left side with the internal capsule omitted; (a) lateral aspect; (b) rostral aspect; (c) caudal aspect. (From W. J. Krieg, *Functional Neuroanatomy*, 2nd ed., Blakiston Div., McGraw-Hill, New York, 1953.)

**putamen**, which is larger and more laterally located, and the **globus pallidus**.

**THE PUTAMEN.** The putamen is the largest of the basal ganglia, and its most rostral part is located lateral to the head of the caudate nucleus, being separated from it by the anterior limb of the internal capsule. A frontal section through this most rostral level (Fig. 11-123) shows a small part of the globus pallidus interposed ventromedially between the putamen and the internal capsule. Slightly more caudally (Fig. 11-124), the putamen assumes more the shape of a thick,

laterally located shell-like covering to the globus pallidus ventrally and the internal capsule dorsally. At this point the body of the caudate nucleus is already displaced a bit more dorsally in its position adjacent to the lateral ventricle. A horizontal section of the brain reveals the entire rostro-caudal extent of the putamen and its relationship to the external capsule, claustrum, and insula, located laterally (Fig. 11-125).

**GLOBUS PALLIDUS.** The globus pallidus forms the more medial part of the lentiform nucleus (Fig. 11-122, C) and it is separated

**Fig. 11-123.** Frontal section through rostral part of corpus striatum. Weigert myelin stain. (From Villiger-Addison, courtesy of J. B. Lippincott Co.)

**Fig. 11-124.** Frontal section through basal part of cerebral hemisphere at the anterior commissure. Weigert myelin stain. (From Villiger-Addison, courtesy of J. B. Lippincott Co.)

from the putamen by a thin layer of white matter called the **lateral medullary lamina**. Phylogenetically, it is the oldest part of the corpus striatum, and it receives its name from the fact that the many myelinated fibers that traverse its structure give it a lighter color than that of the putamen or caudate nucleus when observed in fresh preparations. The globus pallidus is subdivided into medial and lateral parts by another thin layer of white matter called the internal or **medial medullary lamina**. The posterior limb of the internal capsule lies on the dorsomedial border of the globus pallidus, thereby separating the lentiform nucleus from the thalamus (Fig. 11-125).

#### Fiber Connections of the Corpus Striatum

As a general principle, the putamen and caudate nucleus can be said to receive many afferent connections, and cells in these nuclei project to the globus pallidus, while the globus pallidus gives rise to many efferent fibers that course to lower centers in the neuraxis. Additional afferent and efferent

pathways interconnect the striatum and pallidum with other regions of the brain (see schematic, Fig. 11-126).

**AFFERENT FIBERS TO THE NEOSTRIATUM.** For a long time there was some uncertainty about whether or not cortical regions project to the striatum; however, the recent use of more sophisticated neuroanatomic methods has shown that the caudate nucleus and putamen receive afferent fibers from nearly all regions of the cerebral cortex (Fig. 11-126). These **corticostriate projections** appear to be organized in a topographic manner, although there is considerable overlapping. The sensorimotor areas and the more rostral regions of the cerebral cortex in the frontal lobe project more heavily to the neostriatum than does the occipital lobe. A great majority of the fibers from these more rostral cortical zones interconnect with the more anterior portion of the head of the caudate nucleus and with the rostral parts of the putamen, while projections from the parietal and occipital lobes flow progressively into the more caudal regions of the striatum. Most corticostriate fibers project to the ipsilateral striatum, but some fibers project across the

FIG. 11-125. Horizontal section of right cerebral hemisphere.

corpus callosum to the contralateral caudate nucleus and putamen.

A second source of afferent fibers to the striatum is the substantia nigra. This **nigrostriatal projection** was definitely established with the use of fluorescence techniques that demonstrate the pathways of neurons containing monoamines such as dopamine (Fig. 11-126). Most nigrostriatal fibers arise from nerve cells in the pars compacta of the substantia nigra, but some also come from the pars reticulata. Those from the more caudal parts of the substantia nigra project to the putamen, while those from the more rostral parts course to the head of the caudate nucleus. The nigrostriatal pathway is considered the principal source of dopamine for the corpus striatum, and its destruction is thought to be importantly related to the etiology of Parkinson's disease.

A third afferent pathway to the striatum originates in the intralaminar nuclei of the thalamus. Other thalamic nuclei, such as the midline nuclei and the nucleus medialis dorsalis, also contribute fibers to this **thalamostriatal projection**. This projection appears to be topographically organized, with the centromedian and parafascicular nuclei sending fibers to more caudal parts of the putamen and the other intralaminar nuclei projecting to the caudate nucleus more anteriorly in the striatum (Fig. 11-126). Finally, other afferent fibers to the striatum arise in the **raphe nuclei** in the mesencephalon of the brain stem. This latter pathway is probably involved in the maintenance of the high level of serotonin found in the putamen.

**EFFERENT FIBERS FROM THE NEOSTRIATUM.** Efferent fibers from the striatum course to the globus pallidus and the substantia nigra

**FIG. 11-127.** Schematic diagrams showing the origin of fibers forming the ansa lenticularis (ansa lent.) and lenticular fasciculus (lent. fasc.) in the monkey. The ansa lenticularis arises from the outer portion of the medial pallidal segment, lateral to the medial medullary lamina (dashed line), and courses rostrally, ventrally, and medially. The lenticular fasciculus arises from the medial pallidal segment, medial to the medial medullary lamina, and courses dorsally and medially through the internal capsule. CL, subthalamic nucleus (corpus Luys); FX, fornix; IC, internal capsule; LPS, lateral pallidal segment; MPS, medial pallidal segment; SN, substantia nigra. (From Kuo and Carpenter, 1973.)

Pallidofugal fibers to the mesencephalon include projections from the globus pallidus to the pars reticulata of the substantia nigra and to the large-celled red nucleus. No pallidofugal fibers have been traced to more caudal levels of the brain stem or to the spinal cord.

**FUNCTIONAL COMMENT.** The motor functions of the basal nuclei were initially recognized by studies of patients suffering from a large number of movement disorders such as tremors, involuntary movements, and akinesias, and then correlating these clinical observations with the existence of lesions in these forebrain structures. Because the pathways involved are outside the classic pyramidal or great efferent motor pathway, the basal ganglia were considered the principal parts of the so-called "extrapyramidal motor system," and their effects on motor behavior were thought to result primarily from descending influences on lower motor centers. Today, however, it is known that the basal ganglia more closely interact with the cerebral cortex and thalamus than with motor centers in the brain stem and spinal cord, and that the influences exerted by the corpus striatum on motor function occur much higher in the neuraxis than was previously suspected. Much also has been learned in recent years about the transmitters and neurochemical mechanisms that underlie the functions of the basal ganglia, but a true understanding of how the basal ganglia participate in integrated normal motor behavior awaits elucidation.

### The Claustrum

The claustrum is a thin layer of gray matter interposed between the insula and the putamen (Fig. 11-125). It is separated medially from the putamen by a lamina of white matter called the **external capsule**, and its lateral surface, being somewhat irregular and following the gyri and sulci of the insula, is separated from the outer gray cortex of the insula by a layer of white fibers called the **extreme capsule**. The claustrum has been variously considered a part of the insula or a part of the corpus striatum, and although its functional significance is unknown, there is good evidence to suggest that widespread regions of the cerebral cortex project onto the claustrum in a manner similar to projections from the cerebral cortex to the striatum.

### CEREBRAL CORTEX

The cerebral cortex is a mantle of gray substance that covers the cerebral hemispheres. Study of its substance has generated great interest among neuroscientists because many of the more abstract neural functions appear to be related to the activity of its cellular layers. Its complexity, however, still defies a true understanding of the

mechanisms by which information received by the brain is analyzed, stored, retrieved, and utilized to effect an appropriate response. Sophisticated microscopic and ultrastructural anatomic techniques have led to detailed descriptions of the cellular geometry of cortical elements, estimates of the volume of cortical substance, and even computations of the numbers of neurons that the cerebral cortex contains. The fact that cortical neurons are arranged in certain laminar patterns and various regions of cortex display differences in these patterns has been recognized for well over a century. It is customary to consider cortical regions that are phylogenetically older as comprising the **archeocortex**, or **paleocortex**, and others that are phylogenetically more recent as the **neocortex**. Because the cortices of the archeopallium and paleopallium have a rather wide variation in histologic structure in different regions, they are often referred to as **allocortex**. The neocortex, in contrast, shows a more similar histologic pattern in different regions and is called **isocortex**.

The archeocortex is characterized by a basic three-layered structure (polymorphic, pyramidal, and molecular), and it includes the cornu ammonis, dentate gyrus, and the subicular extension of the parahippocampal gyrus (Figs. 11-117; 11-118). During development it commences on the dorsomedial aspect; it then moves ventrally and becomes folded to form the hippocampus (Figs. 11-112; 11-113). The primordium of the paleocortex arises more ventrolaterally in the developing cortex and moves medially with the elaboration of the neocortex to form a transitional cortical region that includes the three-layered prepiriform and periamygdaloid (or piriform) areas, as well as the five-layered entorhinal area (area 28) which constitutes much of the parahippocampal gyrus. With continued development, the more primitive cortical structures migrate to ventromedially located sites, so that most of the dorsal and lateral walls of the pallium located between the archeocortex and paleocortex become neocortex (or neopallium) (Fig. 11-112), and this is characterized by a typical six-layered structure.

### Structure of the Neocortex

In man, the largest part of the cerebral cortex consists of neocortex. Although certain differences are found in various cortical re-

gions, a six-layered schema can usually be recognized in sections that have been cut vertically through the gray substance and have been stained to show the morphology of the nerve cell bodies (such as with the Nissl<sup>1</sup> staining technique) (Figs. 11-128; 11-129). From the surface of the brain inward, the layers are as follows:

**I. MOLECULAR LAYER.** This outermost layer, also called the *plexiform layer* or *lamina zonalis*, is found immediately beneath the pia mater. It is a narrow zone of white substance composed largely of tangentially coursing fibers derived from nerve cells of deeper layers and directed parallel to the surface of the cortex (Fig. 11-128). Within the molecular layer are the terminal fibers of the apical dendrites of the pyramidal cells, as well as other fibers of cells from the subjacent layers. Scattered among the nerve fibers are a small number of nerve cells, which include cells with short axons as well as the **horizontal cells** (of Cajal), the axes of which are oriented parallel to the cortical surface among the processes of the apical dendrites.

**II. EXTERNAL GRANULAR LAYER.** The external granular layer contains large numbers of rather densely packed granule cells and some small pyramidal cells, the apical dendrites of which course superficially into the molecular layer and the axons of which descend into deeper cortical layers (Figs. 11-128; 11-129). Also coursing through the external granular layer are the apical dendrites from pyramidal cells of deeper layers, which are bound for the outermost or molecular layer.

**III. EXTERNAL PYRAMIDAL LAYER.** The external pyramidal layer consists principally of medium-sized and large pyramidal cells. These are arranged so that the smaller pyramidal cells are in the more superficial part, closer to the external granular layer, while the larger pyramidal neurons are located more deeply in this layer (Figs. 11-128; 11-129). The apical dendrites of the pyramidal cells also course superficially toward the molecular layer, and among the pyramidal cells in the external pyramidal layer are some granule cells and the through-going apical dendrites of even more deeply located pyramidal cells. Also located in this layer, as well as in others, are some small multipolar cells with short branching dendrites called

<sup>1</sup>Franz Nissl (1860-1919): A German neurologist and neuroanatomist (Heidelberg).

**Fig. 11-128.** A diagram showing the layers of cells and fibers in the gray substance of the cortex of the human cerebral hemisphere, according to the histologic methods of Golgi, Nissl, and Weigert. A, Stained by the method of Golgi; B, by that of Nissl; C, by that of Weigert. (After Brodmann.)

the **cells of Martinotti**,<sup>1</sup> whose axons course toward the molecular layer with the apical dendrites of the pyramidal cells.

**IV. INTERNAL GRANULAR LAYER.** The internal granular layer is a densely packed lamina containing many granule or stellate cells that have short axons (Fig. 11-128). Among these cells is found a scattering of small pyramidal cells and some vertically oriented neuronal processes traversing the internal granular layer on their way to more superficial layers. Additionally, the internal granu-

lar layer contains a well-defined collection of horizontally arranged nerve fibers that is called the **external band of Baillarger**<sup>2</sup> (Fig. 11-128).

**V. INTERNAL PYRAMIDAL LAYER.** Sometimes called the ganglionic layer, the internal pyramidal layer is composed principally of large and medium-sized pyramidal cells, the apical dendrites of which are directed toward the molecular layer (Fig. 11-128). This layer also contains many of the fine basal

dendrites of the pyramidal cells, processes of neurons from other layers, a few granule cells, and some cells of Martinotti. The largest of the pyramidal cells in the precentral motor cortex are called the **giant cells of Betz**<sup>1</sup> (Fig. 11-130). The internal pyramidal layer also contains a well-defined plexus of horizontally oriented nerve fibers referred to as the **internal band of Baillarger**. The axons of the large pyramidal cells enter the white matter as the corticofugal projection fibers.

**VI. MULTIFORM LAYER.** The multiform layer contains many neurons of different

shapes, including some spindle-shaped cells, cells of Martinotti, and other neurons that have a fusiform shape (Fig. 11-128). At times this layer is subdivided into an outer or superficial lamina and an inner, deeper lamina which gradually merges with the subcortical white matter. Many axons of the cells in the multiform layer enter the subjacent white matter.

#### Cytoarchitectonics and Myeloarchitectonics

Various regions of the cerebral cortex show differences in morphologic structure, and on the basis of these variations, detailed

<sup>1</sup>Vladimir A. Betz (1834-1894): A Russian anatomist (Kiev).

**Fig. 11-130.** Photomicrograph showing a group of giant pyramidal cells whose neuron cell bodies are located in the internal pyramidal layer (layer V). Note that these nerve cells extend their apical dendrites upward through the more superficial layers of the cortex and many reach the molecular layer (Golgi method.)

studies have identified numerous cortical areas with respect to differences in the cellular structure of the various neuronal layers (cytoarchitectonics) or variations in the arrangement of the myelinated fibers in different regions (myeloarchitectonics). Utilizing light microscopic techniques for the study of stained sections of the cerebral cortex, investigators such as Campbell (1905), Brodmann (1909), Vogt and Vogt (1919), von Economo (1929), Rose (1935), and Bailey and von Bonin (1951) distinguished different numbers of cortical areas based on the cellular and fiber patterns of the cortical laminae.

Campbell (1905) identified six cortical layers according to the morphology of the principal neuronal cell type found within each layer, and he recognized about 20 different cortical fields. Brodmann (1909) also differentiated six cortical layers that generally are similar to those of Campbell, and it is Brodmann's schema that is most commonly utilized today and is adopted here. Additionally, Brodmann mapped 47 different cortical fields as the result of his cytoarchitectonic studies: these are shown in Figure 11-131, A and B. Vogt and Vogt (1919) and von Economo and Koskinas (1925) elaborated on the Brodmann maps and identified far greater numbers of cortical fields. The Vogts described over 200 cortical areas on the basis of differences in the patterns made by the myelinated fibers, and von Economo and Koskinas listed over 100 areas. Later von Economo (1927) grouped the neocortical fields into five fundamental types based principally on the cytoarchitectural patterns of the granule and pyramidal cells. These were called **agranular**, **frontal**, **parietal**, **polar**, and **atypical granular** types (Fig. 11-132). The frontal, parietal, and polar types all have six distinguishable laminae that may vary in thickness, but are generally similar in cytoarchitecture and, therefore, are called **homotypical neocortex**. The cytoarchitecture of the agranular and atypical granular cortical areas varies markedly from the pattern seen in the homotypical neocortex and sometimes the term heterotypical neocortex is used for them.

**AGRANULAR TYPE.** The agranular cortex (type 1) is characterized by its great thickness, by the lack of distinct layers of granule cells (layers II and IV), and by the large size and number of pyramidal cells (Fig. 11-132). The granular cells in layers II and IV have been replaced predominately by pyramidal cells. In addition to other sites, the agranular type of neocortex is found in the posterior part of the frontal lobe, just rostral to the central sulcus, and is generally considered the cortical type forming the motor area of the precentral gyrus (Fig. 11-133).

**FRONTAL TYPE.** The frontal type (type 2) of neocortex shows the typical six-layered pattern; it is relatively thick and has medium- to large-sized pyramidal cells in layers III and V (Fig. 11-132). Distinct granular layers (II and IV) are seen, but these are rather narrow. Although this architectonic pattern appears typically in regions of the frontal

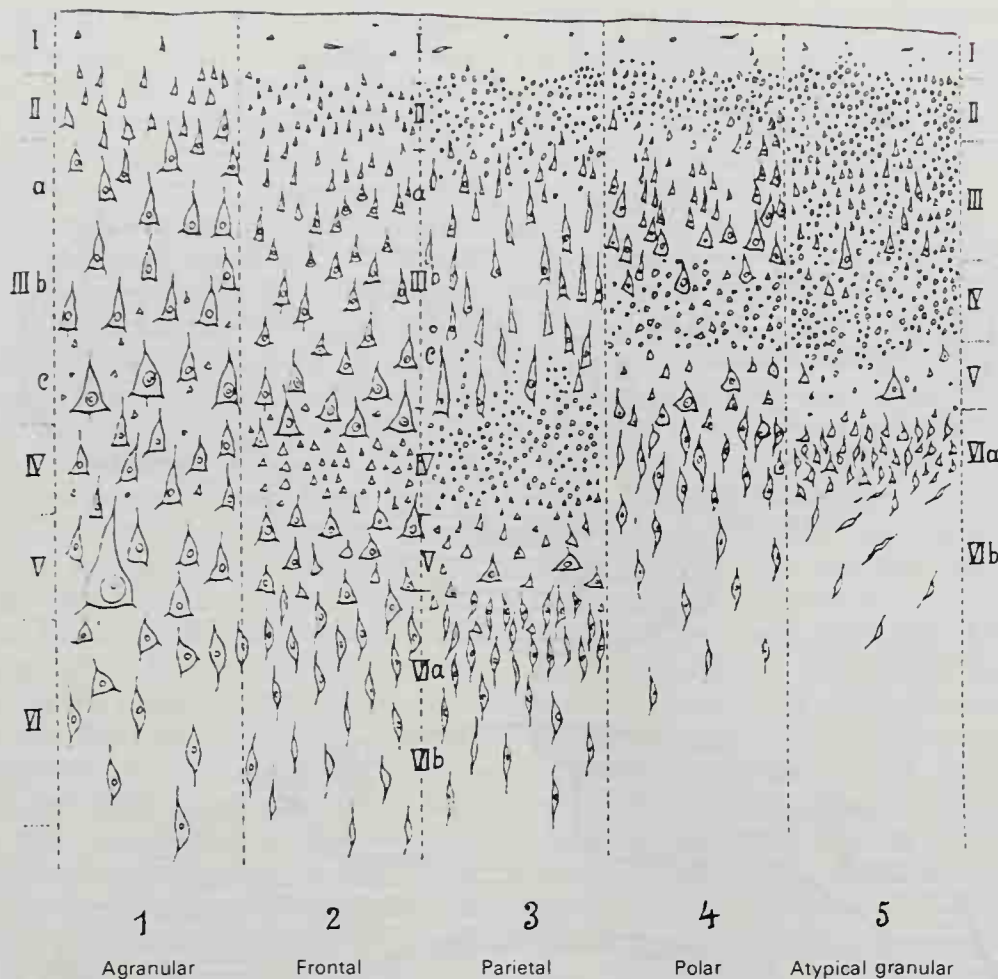

**FIG. 11-131.** The cytoarchitectonic areas of the human cerebral cortex, as seen from the superolateral (A) and medial (B) surfaces of the cerebral hemisphere as described by Brodmann. The different areas are defined by various symbols and enumerated in the order that Brodmann studied them. (From K. Brodmann, *Vergleichende Localisationslehre der Grosshirnrinde*, J. A. Barth, Leipzig, 1909.)

lobe rostral to the motor areas, it also appears in other cortical regions (Fig. 11-133).

**PARIETAL TYPE.** The parietal type (type 3) of neocortex has wider and well developed granular layers (Fig. 11-132). In contrast, the pyramidal cell layers are thin and contain pyramidal cells that are smaller and more slender than those in the frontal type of cortex. This cortical type is found in both the parietal and temporal lobes (Fig. 11-133).

**POLAR TYPE.** The polar type (type 4) is found at both the frontal and occipital poles of the cerebrum (Fig. 11-133). Although it shows a characteristic six-layered pattern, this cortex is thinner overall, the pyramidal cell layers being especially reduced in width and the granular cell layers rather well developed (Fig. 11-132). The polar cell layers of the frontal lobe have more pyramidal cells than those in the occipital lobe.

**Fig. 11-132.** The five types of cortical structure, showing differences in laminar thickness and cellular constituents of the various layers. See text for further details. (From C. von Economo, *Zellaufbau der Grosshirnrinde des Menschen*, J. Springer, Berlin, 1927.)

**ATYPICAL GRANULAR CORTEX.** Also known as **koniocortex**, the atypical granular cortex (type 5) contains large numbers of densely packed granule cells in layers II, III, and IV (Fig. 11-132). Layer III (external pyramidal layer), which in the typical six-layered neocortex contains large numbers of pyramidal cells, contains only a small number of these cells in granular cortex. Overall, the koniocortex is the thinnest of the five neocortical types, and in addition to being found at other sites, it can be seen bounding the calcarine fissure and occupying the most rostral part of the postcentral gyrus (Fig. 11-133).

#### Principal Functional Cortical Areas: Sensory

The localization of function in different cortical regions has been a field of great interest in neurophysiology for many decades. Although neuroscientists have been unable to apply a functional significance to all of the many anatomically recognized parcels of

cerebral cortex that have been described by cytoarchitectonic and myeloarchitectonic methods, it can be said that primary sensory receiving areas characteristically have well-developed granular layers that contain great numbers of densely packed small cells, while the motor areas have many large pyramidal cells. Cortical regions do not function in isolation, and the diagrammatic maps frequently used to illustrate cortical localization must be accepted with a degree of caution. To what extent the cytoarchitecture of different cortical regions and the morphologic geometry of cortical neurons are related to cortical function is unclear, but it would be surprising if the variations in laminar structure from region to region have little to do with the mode of operation of the cerebral cortex. Appearing in recent years are reports of detailed studies of cortical neurons and their precise somatosensory or visual inputs and analyses of unitary discharge patterns of pyramidal neurons associated with specific movements. Such efforts

**FIG. 11-133.** Distribution of the five types of cortex seen in Figure 11-132, as shown on the superolateral (A) and medial (B) surfaces of the cerebral hemisphere. The types of cortex are: agranular (1), frontal (2), parietal (3), polar (4), and atypical granular (5). (From C. von Economo, *Zellaufbau der Grosshirnrinde des Menschen*, J. Springer, Berlin, 1927.)

are attempts to unravel the complexities of cortical neuronal function in relation to the laminar organization observable anatomically.

Various regions of the cerebral cortex receive impulses arising from receptors located in particular sense organs throughout the body or from nerve fibers supplying the skin and internal organs. These include visual, auditory, olfactory, and gustatory im-

pulses of special sensation, as well as impulses of somatic sensibility or somesthesia. The latter term incorporates various sensations associated with touch and pressure (mechanoreception), warmth and cold, position sense and movement of joints, and pain. The sensory receiving areas in the cerebral cortex have been categorized as **primary receiving areas**, to which project the principal thalamocortical pathways from the tha-

lamic relay nuclei (Fig. 11-134), and **secondary receiving areas**, which are located near the primary areas but are distinctly separated from the cortical zones receiving the principal thalamic projection (Fig. 11-135). The secondary areas are usually smaller than the primary areas and do not appear to be organized in the same manner. Primary somesthetic, visual, auditory, and olfactory areas have been localized, as have secondary somesthetic, visual, and auditory areas. Taste and vestibular projections to the cerebral cortex have not been localized as clearly, but are believed to exist.

#### PRIMARY SOMESTHETIC RECEIVING AREA.

The primary somatic sensory area (SI or SmI) is located in the postcentral gyrus and consists of areas 3, 1 and 2, which Brodmann identified as having different cytoarchitectural patterns (Fig. 11-136). In the human brain, area 3 of the primary somesthetic area extends to the floor of the central sulcus, where it becomes continuous with the primary motor cortex (Brodmann's area 4; Msl). Sometimes this transitional zone is called area 3a, while the main part of area 3 is called area 3b. Caudal to area 3 and oriented longitudinally along the crest of the postcentral gyrus is area 1. Behind this is located another longitudinally oriented narrow strip,

area 2, which extends along the posterior wall of the postcentral gyrus to the postcentral sulcus. This latter sulcus separates the primary somesthetic area anteriorly from Brodmann's areas 5 and 7 in the superior parietal lobule posteriorly (Fig. 11-131). Although the primary somesthetic area is a six-layered cortex, it is thinner than the adjacent motor cortex and contains well-developed granular layers. Area 3 differs from areas 1 and 2 because layer III is composed almost completely of granule cells and layer V is poorly developed—characteristics typically seen in cortical sensory receiving areas. Thus, areas 2 and 1 are thicker than area 3, have somewhat less densely arranged granule cells, and contain more pyramidal cells in layers III and V.

It has been well established that the primary somesthetic area receives direct and precise projections from the nucleus ventralis posterolateralis (VPL) and the nucleus ventralis posteromedialis (VPM), which relay afferent impulses to the cortex from the ascending spinothalamic and trigeminal tracts and from the medial lemniscus. The representation of the body in the postcentral gyrus is arranged somatotopically, so that the contralateral lower limb is localized uppermost in the gyrus and extends onto the

**Fig. 11-134.** The lobes of the left hemisphere, showing a few of Brodmann's cortical areas by numbers. Indicated by stippling are the primary cortical receiving areas for somatosensory, visual, and auditory impulses, while the primary motor area is lined. Note the areas are only shown from this superolateral view of the cerebrum and this diagram should be compared with Figure 11-135. (From W. Penfield and L. Roberts, *Speech and Brain Mechanisms*, Princeton University Press, Princeton, 1959.)

**Fig. 11-135.** The primary sensory receiving areas (stippled) and motor areas (lined) of the left hemisphere. Secondary somatosensory and visual areas and the supplementary motor area are also indicated on the medial surface of the cerebrum. The temporal lobe has been cut and turned down to reveal the primary auditory area. (From W. Penfield and L. Roberts, *Speech and Brain Mechanisms*, Princeton University Press, Princeton, 1959.)

medial surface of the cerebrum, where the representation of the genitalia and the bladder is also located. These are followed laterally on the convexity of the gyrus by the areas of localization for the contralateral trunk, upper limb, face, oral cavity, pharynx, and intra-abdominal organs, in that order (Fig. 11-137). The cortical representation of the different regions of the body is not uniform; for example, the foot, hand, and face areas are disproportionately large. The cortical volume allotted to a specific body part is related to the density of the peripheral innervation and not to the size of the region.

The general plan of representation of different body parts has now been extended by detailed studies utilizing microelectrode recordings of the activity of single cortical neurons. It has been shown that neurons in area 2 of the postcentral gyrus respond principally to input from receptors that are activated by the rotation of joints or by the mechanical stimulation of deep tissues, such as the periosteum or fascia, and nerve cells in areas 3b and 1 respond, respectively, to slowly adapting cutaneous receptors. Neu-

rons in area 3a, located adjacent to the motor cortex, respond to stretch afferents. Thus, an anteroposterior representation of modalities exists in the postcentral gyrus (Mountcastle and Powell, 1959a and b; Powell and Mountcastle, 1959). Additionally, there is a complete representation of the body mediolaterally in each of the cytoarchitectonic subdivisions, 3b, 1, and 2, and probably even in 3a of the postcentral gyrus (Fig. 11-138) (Merzenich et al., 1978; Kaas et al., 1979).

#### **SECONDARY SOMESTHETIC RECEIVING AREA.**

A secondary somatosensory area (SII) is located in the cortex of the parietal lobe, behind the lower part of the postcentral sulcus and along the superior bank of the lateral sulcus (Figs. 11-134; 11-146). It is smaller than the primary sensory area and is also somatotopically organized; however, the localization is less discrete than that in SI and there is considerable overlap of the dermatomes. Another distinguishing feature of the secondary somatic sensory area is that both ipsilateral and contralateral body parts are represented in a single somatotopic pattern, in contrast to the strictly contralateral repre-

**Fig. 11-136.** Postcentral cortical areas, 3, 1, and 2 and precentral areas 4 and 6 are shown on the superolateral (A) and medial (B) surfaces of the human cerebrum, described by Brodmann on the basis of different cytoarchitectonic features. (From K. Brodmann, *Vergleichende Localisationslehre der Grosshirnrinde*, J. A. Barth, Leipzig, 1909.)

sensation in SI. The existence of SII was initially discovered in the cat by Adrian (1941), but its presence has subsequently been verified in infrahuman primates and in man. There is also evidence that reciprocal neural connections exist between the primary and secondary somesthetic areas.

**PRIMARY VISUAL RECEIVING AREA.** The primary visual receiving area (V-I) in man and other primates corresponds to area 17 of Brodmann, which is located along the superior and inferior banks and in the depths of the calcarine fissure, and it extends into the cuneus and lingual gyrus (Figs. 11-131; 11-

**Fig. 11-137.** Somatotopic pattern of representation in the primary somesthetic receiving area of the post-central gyrus in the human cerebral cortex. Note the differences in relative size of the cortical regions from which sensations localized to different body parts have been achieved by electrical stimulation. (After W. Penfield and T. Rasmussen, *The Cerebral Cortex of Man*, Macmillan Publishing Co., New York, 1950.)

134 to 11-136). In man, this area is located principally on the medial surface of the occipital lobe, but frequently it continues around the occipital pole to occupy a small but variable portion of the lateral surface of the cerebrum as well. Frequently called the **striate cortex**, the primary visual receiving area may be clearly identified because of the presence of a conspicuous layer of myelinated fibers, limited only to this area, which is called the line of Gennari.<sup>1</sup> This myelinated stria corresponds to the middle of three sublayers in layer IV (Figs. 11-129; 11-139). The striate cortex is quite thin in comparison to other cortical regions, and it is especially rich in granule cells. It contains well developed outer and inner granular layers (II and IV), but the pyramidal cells, except the large **solitary cells of Meynert**,<sup>2</sup> are small. These latter elements, mostly found in

layer V, have a stellate shape and may be considered somewhat modified pyramidal cells that are oriented in a line; they have widely ramifying dendrites and axons that project to the superior colliculus.

The internal granular layer (IV) of the primary visual area (area 17) receives fibers from the lateral geniculate body by way of the geniculocalcarine tract, and the striate area on each side receives input from the contralateral visual half of the visual field, i.e., the temporal half of the ipsilateral retina and the nasal half of the contralateral retina (Fig. 11-140). The macular region of the retina is represented in the more caudal part of the striate region. The geniculocalcarine projections to the striate cortex retain their laterality. The input from the contralateral retina terminates in lateral geniculate layers 1, 4, and 6, while the ipsilateral retinal fibers terminate in lateral geniculate layers 2, 3, and 5. The geniculocalcarine projection courses to layer IV of the striate cortex and is organized in such a manner that neurons from the different geniculate layers terminate in alternating portions of layer IV, each of which measures as much as 0.5 mm wide. Additionally, the striate cortex is organized vertically in columns of cells through all the layers in a manner that also reflects ocular dominance in a right eye-left eye alternating pattern (Fig. 11-141). In a series of elegant studies, Hubel and Wiesel mapped the receptive fields of striate cortical neurons to luminous retinal stimulation. Unlike the circular retinal receptive fields encountered by recording from cells in the lateral geniculate body, the receptive fields for cortical neurons are arranged linearly in the retina, so that cortical cells respond with more or less complexity to slits of light or to edges between light and dark.

**VISUAL AREAS II AND III.** Surrounding the primary visual receiving area are two cortical zones from which evoked potentials can be recorded when the retina is stimulated. These prestriate cortical areas occupy the remainder of the occipital lobes and extend rostrally into the parietal and temporal lobes; they correspond roughly to Brodmann's areas 18 and 19, but are not exactly coextensive with them (Fig. 11-131). Sometimes considered as the visual association cortex, these areas have been shown to be interconnected at the cortical level with the primary visual receiving cortex of area 17. A micro-

<sup>1</sup>Francisco Gennari (1750-1797?): An Italian anatomist and physician (Parma).

<sup>2</sup>Theodor H. Meynert (1833-1892): An Austrian neurologist (Vienna).

**FIG. 11-138.** Microelectrode studies of areas 3b and 1 in the contralateral postcentral gyrus have shown that a complete representation of the body parts exists in each of these two cytoarchitectonic fields. Similar functionally distinct fields have also been reported to characterize the organization of area 2 and are now suspected to exist in area 3a, but these latter two cytoarchitectonic areas are not shown in this figure. This particular map displays the primary somesthetic area in the owl monkey, *Aotus trivirgatus*, but similar results have been reported for many species of monkeys. (From Merzenich, Kaas, Sur, and Lin, 1978.)

electrode analysis of single cell responses has revealed that the retinotopic pattern in area 18 (V-II) is a mirror image of that in area 17. Within area 19, still a third visual receiving area (V-III) exists, and its retinotopic organization also appears to be a mirror image of area 17. Most of the neurons in visual areas II and III respond as "complex" or "hyper-complex" cells according to Hubel and Wiesel, and few if any appear to belong in the "simple" category that has been described in the striate cortex. It is believed that visual areas II and III function by elaborating on the visual input received in the striate cortex and they serve to transfer this information both to other cortical areas and back to brain stem sites. Additionally, they may also play a role in analyzing and coordi-

nating visual information for appropriate environmental and spatial adjustments.

#### **AUDITORY RECEIVING AREAS (AI AND AII).**

The auditory receiving areas are located along the anterior and posterior transverse temporal gyri and correspond to Brodmann's areas 41 and 42 (Fig. 11-131). In man and monkeys, these gyri form part of the temporal operculum and extend from the upper bank of the superior temporal gyrus to the floor of the lateral sulcus, where they lie hidden. To see these areas in the human brain, it is necessary to separate the temporal and parietal opercula, as one does to expose the insula (Fig. 11-135). Much of what is known about auditory receiving areas in the human brain, therefore, has been gained from studies on cats, because these cortical

**FIG. 11-139.** A low power photomicrograph of a parasagittal section of monkey visual cortex stained by the Nissl method for neuronal cell bodies. Note that the visual cortex is a continuous sheet of neurons about 2 mm thick, and in this section it consists of an outer gyrus (A) and a buried fold (B). The arrows indicate the borders between areas 17 and 18. (From D. Hubel and T. Wiesel, 1977.)

**Fig. 11-140.** A simplified diagram of the visual pathway in the human brain. Note that some of the efferent connections between the visual cortex and subcortical structures are shown on the right and that transcallosal fibers interconnect the right and left visual areas. (From R. F. Schmidt, *Fundamentals of Sensory Physiology*, Springer, New York, 1978.)

areas in the cat are located on the exposed lateral surface of the cortex and are easily accessible.

The primary auditory cortex that constitutes area 41 may be described as a highly cellular, six-layered koniocortex with rather thick and densely packed granular layers, similar to the cortex seen in other primary receiving cortical areas. This region (in the cat) is nearly surrounded by a belt of at least three auditory cortical fields (Fig. 11-142), which also respond to auditory stimuli and constitute the secondary auditory area (AII). These latter fields in the cat may be comparable to area 42 in the human brain, located adjacent to area 41. Unlike area 41, however, the six-layered cortex in area 42 is of the parietal type (type 3).

The auditory cortex receives its principal afferent input from the medial geniculate nucleus. These geniculotemporal fibers course by way of the sublenticular part of

the internal capsule and project to both the primary and secondary auditory areas. In the anesthetized monkey or chimpanzee, there is a precise tonotopic localization within the primary auditory receiving area. Studied most extensively in the cat, high tonal frequencies are represented anteriorly in AI, and progressively lower frequencies are represented as one proceeds posteriorly in the primary auditory receiving area. In AII, the tonotopic representation appears to be reversed from that seen in AI, with the higher frequencies being represented more posteriorly and the lower frequencies anteriorly. Some questions have been raised about the precision of this tonotopic representation, however, because microelectrode studies in unanesthetized animals have revealed a more complex response of many cortical neurons in the auditory region than the precise tonotopic organization observed in anesthetized animals. More detailed infor-

**FIG. 11-141.** A dark field autoradiograph taken of area 17 in a macaque monkey in which the ipsilateral eyeball had been injected with tritiated proline-fucose two weeks earlier. The labelled regions stand out in a periodic pattern of white patches in cortical layer IVc as linearly alternating columns, which actually are curving slabs of cortex cut in cross section to the brain surface in this specimen. This demonstrates that the radioactive material injected into the ipsilateral eye had been carried from the retina to alternating specific columns of cells in the ipsilateral striate cortex, between which are gaps of similar width that were not labelled and presumably represent ocular columns for the noninjected contralateral retina. (From D. Hubel and T. Wiesel, 1977.)

mation is necessary before definitive comments can be made about the nature of the organization of the primary and secondary human auditory receiving areas. Interest is currently focused on the columnar organization of the auditory cortex and the manner by which binaural input is processed at a cortical level.

**TASTE OR GUSTATORY RECEIVING AREA.** It is well established that the peripheral pathways mediating special sensory impulses of taste course along special visceral afferent nerve fibers in the facial, glossopharyngeal,

and vagus nerves; however, the central pathways traveled by these impulses are somewhat less clearly understood. Afferent impulses reach the nucleus of the tractus solitarius in the medulla oblongata and are then relayed to higher brain stem, diencephalic, and telencephalic levels. Some evidence appears to indicate that the nucleus of the tractus solitarius projects to a region in the pons located in the parabrachial nuclei within the superior cerebellar peduncle; this has been called the pontine taste area (Norgren and Pfaffmann, 1975). From the

**FIG. 11-142.** The primary (AI, vertical lines) and secondary (AII, cross hatch) cortical auditory receiving areas in the cat. Caudal to the posterior ectosylvian sulcus (ecp) is the posterior ectosylvian area (Ep, dotted), which is structurally distinct from AI and from which only small evoked potentials can be elicited from cochlear nerve stimulation. Below this is the caudal portion of the secondary auditory area (cross hatched and dotted). I, insular region; T, temporal region; ssa, ssm, and ssp, anterior, middle, and posterior parts of the suprasylvian sulcus; eca, anterior ectosylvian sulcus; pss, pseudosylvian sulcus. (From J. E. Rose and C. N. Woolsey, in *Biological and Biochemical Bases of Behavior*, edited by H. F. Harlow and C. N. Woolsey, University of Wisconsin Press, Madison, 1958.)

pons, nerve fibers project to the lateral hypothalamus, the central nucleus of the amygdala, and the medial part of the nucleus ventralis posteromedialis (VPM) in the thalamus. The hypothalamic and amygdaloid projections may be related to feeding behavior, because lesions in these regions markedly alter food intake, whereas the pathway to the thalamus projects to the cerebral cortex.

The cortical areas responsible for the perception of taste are not precisely known; however, a close relationship appears to exist between the cortical receiving areas for general somatic sensations from the tongue and those to which the taste pathways project from the thalamus. Recent information points to the opercular part of the postcentral gyrus, with extensions into the lateral fissure, as one of the cortical taste receiving areas. This region is either within or near the primary somesthetic tongue area. Ablations of the frontal and parietal opercular regions in primates have been reported to result in a loss of taste, while stimulation of the opercular cortex of the parietal lobe in conscious human patients has resulted in the perception of taste sensations.

#### VESTIBULAR CORTICAL REPRESENTATION.

There is reason to believe that impulses traveling along pathways from the vestibular nuclei in the brain stem reach the cerebral cortex because human beings have the ability to perceive consciously their orientation in space. Although studies have revealed cortical cells capable of responding to vestibular input, there does not appear to be a cortical area in which the cells respond only to vestibular impulses. Experiments in cats have implicated a region anterior, but close, to the auditory receiving area. This area includes parts of the anterior ectosylvian and anterior suprasylvian gyri adjacent to the anterior part of the suprasylvian sulcus in this species. More recent experiments in monkeys, however, point to a vestibular receiving area near or within the somatosensory face area in the postcentral gyrus. Cortical neurons in this latter region show a convergence of somatosensory impulses originating from muscles and joints and vestibular impulses. These units also appear to interact with neurons in the motor cortex. The precise pathway(s) by which vestibular information reaches cortical levels is not known, but it is presumed that thalamic or other nuclei lower in the neuraxis are interposed between the primary vestibular nuclei and the cerebral cortex.

#### Principal Functional Cortical Areas: Motor

In addition to its functions related to sensation, the cerebral cortex is importantly involved in the control of movement. Axons arise in deep layers of the cerebral cortex and project to the basal ganglia, thalamus, brain stem, and spinal cord, and many are associated with motor function. Since the initial experiments of Fritsch and Hitzig in 1870, it has been known that electrical stimulation of certain cortical sites in animals and in man can elicit the contraction of individual muscles or muscle groups or inhibit ongoing motor activity. Motor localization studies have identified primary, secondary, or supplementary cortical motor areas, as well as motor areas associated with eye movements and speech. It must be understood that sensory and motor functions of cortical regions are so intimately interrelated that often motor responses can be elicited from stimulation of the so-called sensory areas, and sensory impulses are

**Fig. 11-143.** Lateral view of the cortical areas in the human brain that were reported by O. Foerster to result in motor responses when electrically stimulated. Stimulation of the primary motor cortex (area 4, indicated in solid black) and other parts of the precentral gyrus and the postcentral gyrus (areas 6a  $\alpha$ , 3, 1, and 2; horizontally lined areas) resulted in discrete movements that could be elicited at relatively low thresholds. Stronger electrical stimulation of other regions in the frontal, temporal, and parietal lobes (areas 6a  $\beta$ , 5a and 5b, and 22) resulted in more complex mass movements and turning toward the opposite side; Foerster considered these to be extrapyramidal in their mechanism. Note that Foerster superimposed his results on the cytoarchitectural numbering system utilized by the Vogts, and this differed somewhat from that of Brodmann. (From W. Penfield and T. Rasmussen, 1950, after O. Foerster, 1935).

recordable within the motor regions. Notwithstanding the safety of assuming that the nervous system functions in its entirety in the execution of behavior, there still is ample evidence in support of the concept that a high degree of localization of motor control exists at a cortical level.

**PRIMARY SOMATOMOTOR AREA.** The primary somatomotor area is located in the posterior part of the frontal lobe along the anterior bank of the central sulcus, and it includes most of the adjoining precentral gyrus (Figs. 11-131; 11-134 to 11-136; 11-143). It corresponds to Brodmann's area 4, and its structure is characterized by large numbers of pyramidal cells in layers III and V, by the presence of giant pyramidal cells (of Betz) in layer V, and by its poorly developed external and internal granular layers (II and IV). The primary motor cortex is usually quite thick (3.5 to 4.0 mm) and it is categorized as agranular, belonging to the type 1 grouping. It extends onto the medial surface of the cerebrum, where it occupies the anterior part of the paracentral lobule (Fig. 11-136,B), and on the lateral surface of the cerebrum, it reaches nearly to the lateral fissure but

tapers more narrowly before it ends (Fig. 11-143). It has been estimated that there are between 30,000 and 35,000 Betz cells in the primary motor area, and although their axons join the corticospinal or pyramidal tract, they form only a small percentage of the estimated one million fibers located within that great motor pathway. The giant pyramidal cells may reach sizes of 60  $\mu$ m wide and 120  $\mu$ m high, but many are considerably smaller, especially in the inferolateral or opercular part of the precentral gyrus.

Contraction of specific muscle groups that results in discrete movements of contralateral body parts may be induced by electrical stimulation on the surface of the primary somatomotor area. Much of the information available on the somatotopic pattern of organization in the human motor cortex has been achieved from direct electrical stimulation of the brain during neurosurgical procedures. These studies and others on subhuman primates and other mammals have established that excitation of discrete points of foci will elicit specific motor responses and, by this manner, it has been possible to construct somatotopic maps of the cortical

**Fig. 11-144.** Motor homunculus indicating parts of the body from which motor responses were obtained when area 4 in the precentral gyrus of human patients was electrically stimulated during neurosurgical procedures. (After W. Penfield and T. Rasmussen, *The Cerebral Cortex of Man*, Macmillan Publishing Co., New York, 1950.)

surface on which are represented sequentially the various regions of the body that respond to electrical stimulation (Fig. 11-144). Although some differences have been reported, the lower extremity is represented on the medial surface of the cerebrum in the paracentral lobule and it extends onto the superior part of the precentral gyrus. From this point and continuing laterally along the precentral gyrus, the trunk, arm, forearm, hand, neck, face, lips, jaw, tongue, larynx, and pharynx are represented in sequence. As is true in the primary somatosensory receiving area, there is a disproportionately greater representation in the motor cortex for the hand and face than would be expected on the basis of the size of these body parts (Fig. 11-146). It appears that the more intricate and delicate the capability of motor performance, the greater is the volume of cortical substance required for motor control. The motor field for movements of the thumb is especially large.

It must be emphasized that movement can also be achieved by stimulation of cortical areas other than those in the so-called motor

regions, and the fibers in the corticospinal tract are derived from neurons in the primary somatosensory areas and probably also from cortical areas in occipital and temporal lobes, as well as from other sites in the parietal and frontal lobes. The movements that are elicited by electrical stimulation of the primary motor area are the result of straightforward muscular contractions and never take the form of complex or skilled purposeful actions.

Not much information exists on the functional organization of the motor area; however, it is believed that the cellular elements are organized in a columnar manner as they are in other cortical regions. Recordings from individual units during the performance of a motor task have revealed a complex pattern of interaction among cortical cells. What appears to be represented in the motor cortex is related more to the joint at which the movement occurs and the nature of that movement than to the individual muscles being contracted. Certainly many factors, such as the afferent inputs to the motor region from other cortical fields and other levels of the neuraxis, and the previous experience and learned behavior of the individual, all contribute to the functional organization of the motor cortex.

**PREMOTOR AREA.** The premotor area is a region of the cerebral cortex that extends on both the lateral and medial surfaces of the frontal lobe immediately rostral to the primary motor area. Cytoarchitecturally, it is an agranular, six-layered cortex quite similar to that seen in the motor area, except that it lacks the giant pyramidal cells characteristic of area 4. This entire cortical region, lying behind the frontal association cortex and frontal eye fields and in front of the precentral motor area, was anatomically delineated as area 6 by Brodmann (Figs. 11-131; 11-136); physiologically, however, this region does not appear to function as a single entity. The portion of area 6 that is on the medial surface of the hemisphere has been designated as part of the supplementary motor cortex (Figs. 11-134; 11-145), and that on the lateral cortical surface has been divided into several subareas on both functional and anatomic grounds.

Electrical stimulation of the premotor area gives rise to complex movements, frequently consisting of deviation of the eyes, head, and trunk to the contralateral side, and these are

probably mediated through extrapyramidal paths. Lesions of this region in monkeys and man result in forced grasping. Although there is no general agreement about the portions of area 6 that are responsible for this clinical sign, the best evidence indicates that forced grasping results from lesions of the supplementary motor area located on the medial surface of the hemisphere rather than that part on the lateral cerebral surface. Lesions in the premotor area have also been reported to result in perseveration of a given motor task in monkeys and the inability of human beings to perform correct movements in response to a verbal command.

**SUPPLEMENTARY MOTOR AREA.** The supplementary motor area is located in the medial frontal gyrus on the medial surface of the cerebrum just above the cingulate gyrus and just rostral to the primary motor region that controls movements of the lower extremity (Figs. 11-134; 11-145). It has no specific cytoarchitectural borders and does not contain giant pyramidal cells. It is a physiologically defined region that corresponds to the part of Brodmann's area 6 located on the medial surface of the cerebrum. Electrical stimulation of this region elicits movements of the contralateral extremities in both mon-

**Fig. 11-145.** Diagrammatic representation of the medial (above) and superolateral surfaces of the left cerebrum in the monkey, showing the extent of the primary somatomotor area (precentral motor) and the supplementary motor area. Note the localization pattern within these areas shown in Figure 11-146. (From Woolsey et al., 1952.)

**Fig. 11-146.** Diagram of monkey cerebral cortex showing the general organization plan of the precentral motor cortex (MI), the supplementary motor cortex on the medial surface of the cerebrum (MII), the postcentral primary somesthetic area (SI), and the secondary somesthetic area (SII). (From C. N. Woolsey, in *Biological and Biochemical Bases of Behavior*, edited by H. F. Harlow and C. N. Woolsey, University of Wisconsin Press, Madison, 1958.)

keys and man, but the threshold for these responses is usually higher than that in the primary motor cortex.

In the monkey, the supplementary motor area seems to be organized in a topographic pattern nearly as precise as that seen in the primary motor cortex (Fig. 11-146), whereas in the human brain electrical stimulation appears to elicit complex motor synergies of the eyes, upper extremities and trunk, along with vocalization, and no precise somatotopic pattern has been reported. Lesions in the supplementary motor area of monkeys results in hypertonia, spasticity, and forced grasping without paralysis, while human patients with lesions confined to this region show more subtle motor symptoms, including a reduction in speech, but these are usually transient and recovery of deficits occurs.

**FRONTAL AND OCCIPITAL EYE FIELDS.** It is well established that areas in both the frontal and occipital lobes are functionally related to movements of the eyes. Rostral to the premotor area is a cortical region that produces conjugate eye movements when electrically stimulated. In the human brain, the **frontal eye field** corresponds approximately to Brodmann's area 8, located in front

of the precentral sulcus and occupying the caudal part of the middle frontal gyrus and a portion of the adjacent caudal part of the inferior frontal gyrus (Fig. 11-131). Because the frontal eye field is located immediately anterior to the precentral motor areas that control movements of other facial and oral musculature, some investigators have considered this field a rostral extension of the motor area. It is unclear, however, how this cortical region receives its sensory input, and its functional relationships to brain stem centers that innervate the extraocular musculature are also not well understood. Electrical stimulation of the frontal eye field results in a conjugate deviation of the eyes to the contralateral side of the body. A lesion in this cortical region results in the loss of this motor function and the eyes become deviated toward the side of the lesion because the eye field in the opposite cortex is functioning unopposed.

Electrical stimulation of cortical regions located in the occipital lobe also results in conjugate deviation of the eyes to the opposite side of the body. One **occipital eye field** is more extensive than that found in the frontal lobe and appears to occupy most of striate area 17, and others are located in parts of areas 18 and 19. Stimulation of the striate region above the calcarine fissure appears to evoke lateral and downward movements of the eyes, while stimulation below the fissure results in lateral and upward movements. Efferent projections from the occipital cortex to the superior colliculus and pretectal regions probably serve as the initial part of this corticofugal pathway to the extraocular muscles. The occipital eye fields are thought to be importantly involved in ocular movements required to fix upon and follow a moving object.

**MOTOR SPEECH AREAS.** Although it is believed that certain animals have an ability to communicate by utilizing vocalization and other types of motor performance, communication by the use of language and the motor functions of speech are uniquely human. In most individuals, the cortical areas important for the perception of language and the motor control of speech are confined principally to one of the two hemispheres. Right-handed people have a left cortical dominance for motor skills and most, likewise, have a left hemispheric dominance for the organization and control of

speech. Left-handed or ambidextrous people have a right cortical dominance for most motor skills, but many still have a left hemispheric dominance with respect to speech. Thus, recent studies have indicated that the left hemisphere serves especially for functions related to language and speech, while the right hemisphere serves more importantly for visuospatial and conceptual functions and for other nonverbal skills. As yet, however, there is little definitive morphologic evidence of differences between the two cortical sides. Our understanding of the localization of speech function in the cerebral cortex has principally resulted from studies in people who sustained brain lesions and from reports of electrical stimulation of the brain in conscious patients during neurosurgical procedures.

The **motor speech area of Broca** is located near the operculum of the frontal lobe within the inferior frontal gyrus, just in front of the precentral sulcus (Figs. 11-147; 11-148). It includes the region that coincides approximately with Brodmann's area 44, as well as part of area 45 (Fig. 11-131). Broca's area lies rostral to the primary motor region that controls the laryngeal and oropharyngeal musculature essential for vocalization. Electrical stimulation of this region in the dominant hemisphere may result in the arrest of speech, in aphasic mistakes, or simply in the utterance of vowel sounds. Additionally, alterations in speech behavior have been achieved by stimulation of at least two other cortical regions. One of these is the supplementary motor area on the medial surface of the frontal lobe in front of the primary motor region for the lower extremity, and the other is located in the dominant hemisphere on the lateral surface of the parietal and temporal lobes, the so-called **secondary motor speech area of Wernicke**<sup>1</sup> (Figs. 11-147; 11-148). This latter region occupies a rather large area below the lateral sulcus within the posterior part of the superior temporal gyrus and extends into the supramarginal and angular gyri. It lies adjacent to the auditory receiving area and it is thought to function in speech recognition, because lesions at this site result in receptive aphasia or failure to understand a previously known language.

<sup>1</sup>Karl Wernicke (1848-1905): A German neurologist (Berlin).

**Fig. 11-147.** The dominant (usually left) cerebral hemisphere, showing areas devoted to the elaboration of speech as determined by evidence from electrical stimulation of the human brain during neurosurgical procedures. (From W. Penfield and L. Roberts, *Speech and Brain Mechanisms*, Princeton University Press Princeton, 1959.)

**Fig. 11-148.** Photograph of the dominant left hemisphere of the human brain on the surface of which are indicated the areas devoted to speech. Local injury or electrical stimulation of these areas produces aphasia. White dots outline the central and lateral sulci and the numbers in the temporal lobe mark the centimeters back from the tip of that lobe. (From W. Penfield and L. Roberts, *Speech and Brain Mechanisms*, Princeton University Press, Princeton, 1959.)

## WHITE SUBSTANCE OF THE CEREBRAL HEMISPHERE

The white substance of the cerebral hemisphere underlies the outer laminated mantle of cells that forms the cortical gray substance. Consisting of a great mass of myelinated fibers, this cerebral white substance intervenes between the cortical gray matter and the gray matter of the more deeply located basal ganglia. If a horizontal section of the brain is made deep to the level of the cortical sulci and gyri, but superficial to the corpus callosum, the subcortical white substance on each side may be seen to form a

semioval mass that is called the **centrum semiovale** (Fig. 11-149). The fibers that compose the centrum semiovale are the same as those that form the **corona radiata** (see below) when cut transversely, and they consist of **projection fibers**, which connect the gray matter of the cerebral cortex with the caudal parts of the brain and spinal cord, and association or **arcuate cerebral fibers**, which interconnect different parts of the cerebral cortex of the same side. A third group of fibers, called **commissural fibers**, interconnects regions of the two cerebral hemispheres across the median plane. The

**FIG. 11-149.** A diagrammatic representation of a frontal section of the right cerebral hemisphere seen from above. Note the semioval mass of white matter that forms the centrum semiovale (red arrows) and the limbs and genu of the internal capsule.

commissural fibers comprising the corpus callosum intermesh with the projection and arcuate cerebral fibers at the level of the centrum semiovale, but they can best be seen passing across the midline at the depth of the longitudinal cerebral fissure. Commissural fibers forming the commissure of the fornix (hippocampal commissure), the epithalamic commissure (posterior commissure), and the rostral commissure (anterior commissure) are found more deeply in the cerebrum.

### Projection Fibers

The projection fibers of the cerebral hemisphere include both afferent fibers, which originate in subcortical centers and terminate in the cerebral cortex (**corticopetal fibers**), and efferent fibers, which arise in the cerebral cortex and terminate in lower centers of the neuraxis (**corticofugal fibers**). Certain groups of projection fibers have already been described in previous sections of this chapter, such as the afferent and efferent fibers that constitute the fimbria and fornix

system of the hippocampal formation. Mention has also been made of the cortical interconnections with the brain stem, thalamus, and basal ganglia. Above or superior (rostral) to the thalamus and basal ganglia, these latter interconnections and most of the other fibers conveying information to and from the gray matter of the cerebral cortex become arranged in a radiating mass of white matter called the **corona radiata** (Fig. 11-150). The arrangement of the corona radiata can best be visualized when a careful dorsoventral dissection of the cerebrum is made in the same orientation as that followed by the course of the corticopetal and corticofugal fibers. The corona radiata is continuous caudally with the more compactly formed internal capsule.

**INTERNAL CAPSULE.** The internal capsule is a thick mass of white matter that is bounded laterally by the lentiform nucleus and medially by the head of the caudate nucleus, the dorsal thalamus, and the tail of the caudate nucleus. Caudally (or inferiorly), many of the fibers that comprise the internal capsule form the cerebral peduncles, while

**FIG. 11-150.** Lateral view of a dissection of the left cerebral hemisphere, showing the fanlike arrangement assumed by the corticopetal and corticofugal fibers throughout the hemisphere as they form the internal capsule and the corona radiata.

**FIG. 11-151.** Diagram showing the locations of the various functional groups of fibers in the internal capsule as seen in a horizontal section. (N. B. Everett, *Functional Neuroanatomy*, Lea & Febiger, Philadelphia, 1965.)

rostrally (or superiorly) the internal capsule assumes a more fan-like arrangement and thereby forms the corona radiata (Fig. 11-150). Between the caudate nucleus and the dorsal thalamus, the internal capsule is bent approximately to a right angle around the medial margin of the lentiform nucleus (Fig. 11-151). This angular part of the internal capsule is called the **genu of the internal capsule**. When the internal capsule is studied in horizontal section, it can be seen that the portion rostral to the genu, the **anterior limb** (*crus anterior*), lies between the caudate nucleus medially and the lentiform nucleus laterally. The portion caudal to the genu, the **posterior limb** (*crus posterior*), is interposed between the thalamus medially and the lentiform nucleus laterally. The largest part of the posterior limb is called the **thalamolenticular part** (*pars thalamolenticularis*). The portion of the posterior limb that curves around the caudal end of the lentiform nucleus is called the **retrolenticular part** (*pars retrolenticularis*), and the portion that lies ventral to the lentiform nucleus is the **sublenticular part** (*pars sublenticularis*).

The **anterior limb of the internal capsule** contains **thalamocortical fibers** that comprise the **anterior thalamic radiation**. These fibers are derived from the anterior and medial thalamic nuclei and course to the frontal lobe of the cerebral cortex (Fig. 11-151). **Corticothalamic fibers** coursing from frontal lobe areas to the thalamus and

**frontopontine fibers** interconnecting the frontal lobe to the pontine nuclei are also located in the anterior limb of the internal capsule.

The **genu of the internal capsule** contains, in addition to corticothalamic and thalamocortical fibers, several fascicles of **corticobulbar fibers** to the motor nuclei of the cranial nerves (Fig. 11-151). One group of fibers is derived from the frontal eye fields of cortical areas 8 and 9 and courses to the oculomotor nucleus bilaterally, the trochlear nucleus ipsilaterally, and the abducens nucleus contralaterally. Another corticobulbar fascicle consists of fibers from the face, jaw, and oral cavity regions in the primary somatomotor cortex of area 4. These latter fibers terminate in the motor nucleus of the trigeminal nerve bilaterally, the facial nucleus bilaterally, the nucleus ambiguus bilaterally, and the hypoglossal nucleus contralaterally.

The **thalamolenticular part of the posterior limb of the internal capsule** is the part that is oriented posterolateral to the genu (Fig. 11-151). It contains the **central thalamic radiation**, which consists of thalamocortical somesthetic fibers to both the precentral and postcentral gyri, and corticofugal fibers from the postcentral gyrus (areas 3, 1, and 2) to the thalamus. Also passing through the thalamolenticular part of the internal capsule are the corticospinal and corticorubral fibers. The **corticospinal fibers** are derived from the upper and lower extremity and from trunk

regions of the somatomotor cortex of area 4, and those fibers coursing to the motor nuclei of the muscles of the arm are nearer the genu than are those coursing to the motor nuclei of the muscles of the leg. The *corticorubral fibers* arise in area 6 and course to the ipsilateral red nucleus.

The **retrolenticular part of the posterior limb** contains some fibers of the **posterior thalamic radiation**, including certain geniculocalcarine fibers and others that interconnect the occipital cortex and the pulvinar region of the thalamus. It also contains many corticofugal fibers from areas 18 and 19 that project to visual motor centers in the rostral brain stem. Other corticofugal fibers in the retrolenticular part are derived from association areas located in the parietal and occipital lobes and course to the pontine nuclei.

The **sublenticular part of the posterior limb** contains corticofugal fibers from the parietal and temporal lobes that course to the pontine nuclei, and corticotectal fibers that project to the superior colliculus in the mesencephalon. It also contains the **auditory radiation** from the medial geniculate body, which courses to the auditory receiving area in the transverse temporal gyrus; the **optic radiation** (geniculocalcarine tract) from the lateral geniculate body, which courses to the visual receiving area in the striate cortex of the occipital lobe; and corticofugal fibers from the occipital cortex, which project to the superior colliculus.

A few of the fibers that compose the optic radiation pass in the retrolenticular part of the internal capsule, but most of the geniculocalcarine fibers pass through the sublenticular part. There are some differences in the pathways taken by fibers that course to area 17 from the lateral geniculate body. Geniculocalcarine fibers destined for the superior bank of the calcarine fissure leave the dorsal part of the lateral geniculate body and course almost directly posteriorly to the striate cortex. Fibers from the more ventral parts of the geniculate body, destined for the inferior bank of the calcarine fissure, initially loop forward and downward in the temporal lobe, forming the so-called loop of Meyer<sup>1</sup> or loop of Meyer and Archambault<sup>2</sup>

(Figs. 11-86; 11-152) before turning back to join the other fibers in the optic radiation.

### Arcuate Cerebral Fibers (Association Fibers)

The arcuate cerebral fibers, or association fibers, interconnect the different cortical regions of the same hemisphere. By definition, they are all ipsilateral because the fibers that interconnect cortical areas of the two hemispheres cross the median plane to form the corpus callosum and are referred to as commissural fibers. Arcuate cerebral fibers are of two types: **short arcuate fibers** that interconnect adjacent cortical gyri, and **long arcuate fibers** that interconnect cortical gyri separated by greater distances (Fig. 11-153).

**SHORT ARCUATE FIBERS.** The short arcuate fibers are of two kinds: intracortical and subcortical. The **intracortical short arcuate fibers** commence and terminate within the gray substance. They form bands of both myelinated and unmyelinated fibers within certain cortical layers that interconnect adjacent gyri; they do not enter the subcortical white matter (Fig. 11-128,C). The **subcortical short arcuate fibers** are groups of fibers that leave the gray substance in one gyrus, enter the subcortical white matter, form a U-shaped loop, and curve upward to join the gray substance of an adjacent gyrus (Fig. 11-153).

**LONG ARCUATE FIBERS.** The long arcuate fibers form bundles of varying sizes and lengths and are deeply situated in the subcortical white matter. The longest fibers, which join more widely separated gyri, are generally located in the deepest portions of these fasciculi. Several distinct bundles can be dissected readily and have been given the following descriptive names: the uncinate fasciculus, the cingulum, the superior longitudinal fasciculus, the inferior longitudinal fasciculus, the superior occipitofrontal fasciculus, the inferior occipitofrontal fasciculus, and the perpendicular occipital fasciculus.

The **uncinate fasciculus** has a dorsal and a ventral component. Its ventral part interconnects the gyri on the orbital aspect of the frontal lobe with the cortex of the parahippocampal gyrus and other gyri on the medial surface of the temporal lobe (Figs. 11-152; 11-153). Its dorsal component unites other gyri on the superolateral aspect of the frontal lobe with the cortex of the temporal gyri

<sup>1</sup>Adolf Meyer (1866-1950): An American psychiatrist (New York and Baltimore).

**FIG. 11-152.** Lateral view of a dissection of the left cerebral hemisphere that exposes the anterior and posterior limbs of the internal capsule, as well as the optic radiations. (Courtesy of Dr. Charles F. Bridgman, who drew it from a dissection made by the late Professor A. T. Rasmussen.)

**FIG. 11-153.** Diagram showing the principal systems of arcuate (or association) fibers in the cerebrum.

or the more lateral aspect of the temporal lobe nearer the temporal pole. The uncinate fasciculus is a hook-shaped bundle that curves around the stem of the lateral sulcus deep to the point at which that fissure divides into its rami.

The **cingulum** is a prominent fasciculus that courses along the medial aspect of the cerebral hemisphere and forms much of the white substance within the cingulate gyrus (Figs. 11-153; 11-154). It courses from the subcallosal and parolfactory gyri rostrally, follows the curve of the corpus callosum, and joins the parahippocampal gyrus caudally (Figs. 11-153 to 11-155). Although some fibers course along its entire length, others join the cingulum or leave it to enter other gyri located more dorsally on the medial surface of the cerebrum.

The **superior longitudinal fasciculus** is a large bundle of arcuate fibers that is located deep in the white matter of the cerebrum, along the dorsolateral border of the lentiform nucleus. It courses along virtually the entire anteroposterior extent of the cerebrum. Commencing in the frontal lobe, the superior longitudinal fasciculus extends backward above the insula and through the parietal lobe to the occipital lobe, where it arches downward and forward to disperse within the temporal lobe. The arching nature of this bundle led to its former name of **arcuate fasciculus**.

The **inferior longitudinal fasciculus** interconnects the cortex of areas 18 and 19 in the occipital lobe with the superior, middle, and inferior temporal gyri, the medial and lateral occipitotemporal gyri, and the parahippocampal gyrus of the temporal lobe. It courses near the lateral walls of the temporal (inferior) and occipital (posterior) horns of the lateral ventricle and is separated from them by the optic radiation (Figs. 11-152 to 11-155).

The **superior occipitofrontal fasciculus** (or fronto-occipital fasciculus) passes between the lateral aspect of the caudate nucleus and the site at which the fibers of the corpus callosum interdigitate with those of the internal capsule to form the corona radiata (Fig. 11-154). This bundle of arcuate fibers connects gyri in the occipital and temporal regions with others in the frontal lobe and insula.

The **inferior occipitofrontal fasciculus** lies lateral to the claustrum in the inferior part of the extreme capsule, just dorsal to the uncinate fasciculus (Figs. 11-152; 11-154). It in-

**Fig. 11-154.** A diagram of a coronal section through the brain at the level of the anterior commissure, showing (in solid black) the approximate positions of several of the major long arcuate fiber bundles. (From E. C. Crosby, T. Humphrey, and E. W. Lauer, *Correlative Anatomy of the Nervous System*, Macmillan Publishing Co., New York, 1962.)

terconnects the gyri on the inferolateral aspect of the occipital and temporal lobes with gyri on the inferolateral portion of the frontal lobe.

The **perpendicular occipital fasciculus** runs vertically through the rostral part of the occipital lobe and connects the inferior parietal lobule with the lateral occipitotemporal gyrus of the temporal lobe (Fig. 11-153).

### Commissural Fibers

The commissural fibers in the cerebral white substance include those in the corpus callosum, in the commissure of the fornix, in the anterior (rostral) commissure, and in the posterior (epithalamic) commissure.

### LATERAL VENTRICLES

The lateral ventricles are irregularly shaped cavities located within the lower and medial parts of each cerebral hemisphere, one on either side of the midline (Figs. 11-156; 11-157). Developing prenatally as lateral

**Fig. 11-155.** Lateral view of a dissection of the right cerebral hemisphere, exposing the superior and inferior longitudinal fasciculi and the right optic radiations. (Courtesy of Dr. Charles F. Bridgman, who drew it from a dissection made by the late Professor A. T. Rasmussen.)

**Fig. 11-156.** The ventricles of the brain, projected from within the cerebrum and visualized from the left lateral aspect.

**Fig. 11-157.** The ventricles of the brain, projected from within the cerebrum and visualized from above.

dilatations from the primary cerebral vesicle in the prosencephalon, they are lined by a ciliated epithelial covering called the **ependyma** and they contain cerebrospinal fluid.

In different individuals the lateral ventricles may vary considerably in size and, within the same person, the ventricular walls may be nearly in apposition in one region and quite apart in another (Fig. 11-161). The two lateral ventricles are separated from each other by a thin median vertical partition, the **septum pellucidum** (Fig. 11-162), but each communicates with the third ventricle and thus indirectly with each other through the **interventricular foramen** (of **Monro**) (Figs. 11-156; 11-158; 11-160). Each lateral ventricle consists of a **central part** with three prolongations called the **cornua**

or horns. These are the **frontal** (or **anterior**) **horn**, the **occipital** (or **posterior**) **horn**, and the **temporal** (or **inferior**) **horn** (Figs. 11-156 to 11-159).

**CENTRAL PART.** The central part of the lateral ventricle extends from the interventricular foramen to the splenium of the corpus callosum (Figs. 11-157 to 11-159). It is a curved cavity that lies principally in the parietal lobe; it has a triangular shape in transverse section, with a roof, a floor, and a medial wall. The roof is formed by the undersurface of the corpus callosum. The floor is really an oblique inferolateral wall formed from medial to lateral by the following structures: the fornix, the choroid plexus, the lateral part of the dorsal surface of the thalamus, the thalamostriate vein, the

**FIG. 11-158.** Drawing of a cast of the ventricular cavities, viewed from the side. (Retzius.)

stria terminalis, and the caudate nucleus. The medial wall is formed by the septum pellucidum, which separates it from the opposite lateral ventricle.

**FRONTAL (ANTERIOR) HORN.** From the central part of the lateral ventricle, the frontal or anterior horn passes forward and laterally with a slight inclination downward beyond the interventricular foramen into the frontal lobe (Figs. 11-156 to 11-159). As it curves around the anterior end of the caudate nu-

cleus, its rostral boundary is formed by the genu and rostrum of the corpus callosum. The frontal horn is bounded *medially* by the rostral part of the septum pellucidum, and its *lateral wall*, *inferolateral angle* and much of its *floor* are formed by the head of the caudate nucleus (Fig. 11-162). The remaining medial portion of its floor consists of the curved rostrum of the corpus callosum, and its roof is formed by the rostral part of the trunk of the corpus callosum. In frontal section, the cavity of the frontal horn is triangular.

**OCCIPITAL (POSTERIOR) HORN.** The occipital horn of the lateral ventricle is a somewhat narrowed posterior extension of the central part (Figs. 11-156 to 11-159). Its direction is initially backward and laterally and, as it continues backward, it then curves medially before coming to a point in the occipital lobe (Fig. 11-162). Its roof is formed by the tapetum of the corpus callosum, which consists of fibers passing to the cortex of the temporal and occipital lobes. On the *medial wall* of the occipital horn is located a longitudinal eminence, the **calcar avis**, which is formed by the deep infolding of the calcarine sulcus (Figs. 11-163; 11-164). The forceps occipitalis of the corpus callosum sweeps around to enter the occipital lobe and forms another projection located above the calcar avis called the **bulb of the occipital horn** (Figs. 11-163; 11-164).

**TEMPORAL (INFERIOR) HORN.** The temporal or inferior horn is the largest of the three cornua. It traverses the temporal lobe of the brain, forming a curve around the posterior end of the thalamus during its course (Figs. 11-157 to 11-159). It passes initially posteriorly, laterally, and downward, and then it curves forward to extend within 2.5 cm of the temporal pole. Its direction is fairly well indicated on the surface of the brain by the course of the superior temporal sulcus. Its roof is formed chiefly by the inferior surface of the tapetum of the corpus callosum, but the tail of the caudate nucleus and the stria terminalis also extend forward in the roof of the temporal horn to its rostral extremity. From lateral to medial along the *medial wall* and *floor* of the temporal horn are found the following structures: (1) the longitudinally oriented **collateral eminence** (Figs. 11-163; 11-164), which is an elongated elevation caused by the collateral sulcus that is continuous posteriorly with the flattened **collateral**

**FIG. 11-162.** Horizontal section of the cerebrum, viewed from above, that exposes the frontal (anterior) and occipital (posterior) horns of the right lateral ventricle and the occipital and temporal (inferior) horns of the left lateral ventricle. Note also the tela choroidea of the third ventricle and the choroid plexus of the left lateral ventricle.

**FIG. 11-163.** The occipital (posterior) and temporal (inferior) horns of the left lateral ventricle, exposed from the left side.

**Fig. 11-164.** The occipital (posterior) and temporal (inferior) horns of the left lateral ventricle, opened and viewed from above.

trigone (Fig. 11-164); (2) the **hippocampus**, which is visible as a prominent, curved elevation that is narrow posteriorly but expands anteriorly, where its surface is marked by radial grooves called **hippocampal digitations** (Fig. 11-164); (3) the **fimbria** of the hippocampus, which is located along the medial border of the hippocampus (Fig. 11-164) and is continuous with the hippocampal layer of white matter called the **alveus**.

Partly covering the upper surface of the hippocampus is the inferior or temporal extension of the **choroid plexus** (Figs. 11-162; 11-163). If the choroid plexus is removed, a cleft-like opening is left along the medial wall of the temporal horn. This is the inferior part of the **choroid fissure**.

**CHOROID PLEXUS OF THE LATERAL VENTRICLE.** The choroid plexus of the lateral ventricle, similar to that found in the fourth ventricle, is a highly vascular, fringe-like process of pia mater covered by an epithelial layer of ependymal cells (Fig. 11-165). Projecting into the cavity of the lateral ventricle, it extends posteriorly from the interventricular foramen through the central part of the lateral ventricle, where it lies upon the upper surface of the thalamus (Fig. 11-162). At the interventricular foramen, it is continuous with the choroid plexus of the opposite ventricle (Fig. 11-165), and from the central part of the lateral ventricle it courses downward within the ventricular cavity into the temporal (inferior) horn (Figs. 11-162; 11-163). It does not extend into the frontal (anterior) or occipital (posterior) horns.

The portion of choroid plexus in the central part of the lateral ventricle forms the vascular fringed margin of a triangular process of pia mater called the **tela choroidea of the third ventricle**. The choroid plexus projects into the lateral wall of the lateral ventricle from under the lateral edge of the fornix through a cleft called the **choroid fissure**. The portion of choroid plexus in the temporal (inferior) horn lies in the concavity of the

**Fig. 11-165.** Diagram of a coronal section through the central part of the lateral ventricle and the third ventricle. The pia mater and the tela choroidea (fused double layer of pia mater) are shown in red and the epithelial ependymal lining is shown in green.

**Fig. 11-166.** Diagram of a coronal section through the temporal (inferior) horn of the lateral ventricle. The pia mater is shown in red and the epithelial ependymal lining is shown in green.

hippocampus and overlaps the fimbria hippocampi (Fig. 11-163). From the lateral edge of the fimbria the epithelium of the choroid plexus is reflected onto the roof of the temporal horn (Fig. 11-166).

The choroid plexus consists of minute villous processes or tufts of blood vessels brought into the tela choroidea by the pia mater. The tufts are covered everywhere by a layer of epithelial cells derived from the ependyma. The arteries of the choroid plexus in the lateral ventricle are (a) the **anterior choroidal artery**, a branch from the cavernous portion of the internal carotid artery that enters the choroid plexus at the end of the temporal (inferior) horn, and (b) several **posterior choroidal arteries**, which are branches of the posterior cerebral arteries and pass forward under the splenium of the corpus callosum. The **choroidal veins** draining the choroid plexus unite to form a tortuous vein that flows rostrally to the interventricular foramen. Here they join the **thalamostriate vein** to form the **internal cerebral vein**.

The **choroid fissure** is the cleft-like space that is produced when the choroid plexus is pulled away and the continuity between the ependyma of the choroid plexus and the epithelium lining the ventricle (i.e., the line of invagination of the choroid plexus) is severed. Like the choroid plexus, the choroid fissure extends from the interventricular foramen to the tip of the temporal (inferior) horn (Fig. 11-166). The upper part of the fis-

sure nearest the interventricular foramen is situated between the lateral edge of the fornix and the upper surface of the thalamus (Fig. 11-165). More posteriorly, near the commencement of the temporal (inferior) horn, the choroid fissure lies between the fimbria hippocampi and the caudal end of the thalamus. In the remainder of the temporal (inferior) horn, the fissure is located between the fimbria in the ventricular floor and the stria terminalis in the roof (Fig. 11-166).

The **tela choroidea of the third ventricle** is a fused double fold of pia mater, triangular in shape, that lies beneath the fornix (Fig. 11-162). The lateral portions of its lower surface rest upon the thalami, while its medial portion is in contact with the ependymal roof of the third ventricle (Fig. 11-165). The apex of this triangular fold is situated at the interventricular foramen, while its base is located posteriorly at the level of the splenium of the corpus callosum and occupies the interval between the corpus callosum above and the colliculi of the mesencephalic tectum and pineal body below. Its lateral margins are modified to form the highly vascular choroid plexuses of the lateral ventricles (Figs. 11-162; 11-165). After removal of the tela choroidea, an interval sometimes called the **transverse fissure of the brain**, is opened between the splenium above and the mesencephalic tectum below.

From the inferior surface of the tela choroidea, a pair of vascular fringed processes, the **choroid plexuses of the third ventricle**,

project downward, one on either side of the midline (Fig. 11-165). These invaginate the ependymal roof of the third ventricle to achieve the cavity of that ventricle.

### **Blood Supply of the Prosencephalon**

The prosencephalon receives its arterial blood supply from the internal carotid arteries as they enter the cranial cavity and from the posterior cerebral arteries, formed by the bifurcation of the basilar artery on the ventral aspect of the brain stem at the pontine-mesencephalic junction (Fig. 11-167). Thus, the neuraxis rostral to the midbrain is served by branches of vessels that participate in the formation of the *circulus arteriosus cerebri* or the cerebral arterial circle of Willis.<sup>1</sup> The vessels that supply the

<sup>1</sup>Thomas Willis (1621-1675): An English physician, neurologist, and anatomist (London).

diencephalon and the telencephalon are derived from the **posterior cerebral** branches of the **basilar** artery, the **posterior communicating**, **anterior choroidal**, **middle cerebral**, and **anterior cerebral** branches of the **internal carotid** artery, as well as a few penetrating vessels that branch directly from the internal carotid to supply the infundibular region of the hypothalamus.

### **Posterior Cerebral Artery**

Although the posterior cerebral arteries in the adult brain commence as the terminal branches of the basilar artery, it should be stressed that as a supratentorial vessel, this artery develops as a branch of the internal carotid artery. In about 20% of patients studied by cerebral angiograms, the posterior cerebral artery originates as a branch of the internal carotid artery, thereby reflecting its

**FIG. 11-167.** The arterial cerebral circle (of Willis), formed by the posterior, middle, and anterior cerebral arteries and the posterior and anterior communicating arteries. Note the centrally penetrating vessels from the posterior communicating artery, the anterior choroidal artery, the anterolateral central arteries (lenticulostriate), and the long central artery (recurrent artery of Heubner). (From L. A. Gillilan in *Correlative Anatomy of the Nervous System*, edited by E. C. Crosby, T. Humphrey and E. C. Lauer, Macmillan Publishing Co., New York, 1962.)

developmental origin (Fig. 11-168). It makes its appearance rather late in development, coincident with the period of posterior expansion of the forebrain. As prenatal brain growth continues, the posterior communicating arteries regress in size, and the stem and terminal branches of the posterior cerebral arteries gradually shift caudally and become dependent on the vertebrobasilar system.

In the adult the posterior cerebral artery supplies the upper pons and midbrain, the posterior hypothalamus, posterior thalamus, much of the inferomedial aspect of the temporal lobe, and most of the occipital lobe. Perhaps more than any other vessel, it supplies those regions of the brain that are responsible for visual motor behavior and visual perception. It has been pointed out (Hoyt, Newton and Margolis, 1974) that the posterior cerebral artery serves the compre-

hensive functions of seeing and looking by supplying: (1) the mesencephalic and pontine regions concerned with pupillary reflexes, convergence, vertical and horizontal eye movements, vestibulo-ocular reflexes, and various corneal, palpebral, and facial reflexes; (2) the lateral geniculate body and pulvinar, which transmit and modulate retinal impulses; (3) the splenium of the corpus callosum, which is the portion of the large interhemispheric commissure that transfers visual information across the cerebral hemispheres; (4) the inferior part of the temporal lobe that is concerned with the storage and retrieval of visual data (memory); (5) cortical area 17, the visual or striate cortex, which receives and processes visual input; and (6) parts of cortical areas 18 and 19, the peristriate cortex, which elaborate on the visual input and, in turn, transmit information to other cortical areas and additionally act on

**Fig. 11-168.** Diagrammatic representations of the basic neural tube brain regions (above) and the superimposed four large branches of the internal carotid artery (below). Note that during early development the posterior cerebral artery depends on the internal carotid circulation, but later it shifts to the vertebrobasilar circulation (latter not shown.) Observe that the ventromedial and ventrolateral perforating vessels from the large branches of the internal carotid artery supply the basal cell mass, while dorsally directed vessels supply the cerebral cortex, (From H. A. Kaplan, in *Handbook of Clinical Neurology*, Vol. 11, edited by J. P. Vinken and G. W. Bruyn, American Elsevier, New York, 1972.)

the mesencephalic oculomotor systems. The initial or circular segment of the posterior cerebral artery consists of a *precommunical* part and a *postcommunical* part, while the cortical segment is called the *terminal* part.

**PRECOMMUNICAL PART.** The precommunical part of the circular segment of the posterior cerebral artery is usually less than 1.0 cm long; it extends from its origin at the basilar bifurcation laterally to the point of junction of the posterior communicating artery (Fig. 11-167). From this part the **central posteromedial arteries** are derived. These include: (a) three to six *interpeduncular branches*, which penetrate the floor of the interpeduncular fossa through the posterior perforated substance to supply the upper midbrain (substantia nigra, red nucleus, oculomotor nucleus, and oculomotor and trochlear nerves) and the caudal hypothalamus; and (b) the *quadrigeminal branches*, which course around the brain stem to supply the region of the superior colliculus and extend rostrally to help supply the medial geniculate nucleus.

Posterior thalamoperforating and medial posterior choroidal arteries usually arise

from the precommunical part of the posterior cerebral artery, but may arise more laterally from the postcommunical part. The posterior thalamoperforating arteries penetrate the posterior perforated substance to supply the posterior part of the thalamus. After branching from the posterior cerebral artery, the medial posterior choroidal artery parallels the course of the posterior cerebral artery around the brain stem and sends branches to the quadrigeminal plate and the pineal gland. It then courses rostrally along the roof of the third ventricle, where it helps to supply the choroid plexuses of the lateral and third ventricles and the tela choroidea.

**POSTCOMMUNICAL PART.** The postcommunical part of the circular segment of the posterior cerebral artery commences at the junction of the posterior communicating artery and courses posteriorly around the brain stem to reach the tentorial surface of the cerebrum, where it becomes the terminal part after dividing into cortical branches (Figs. 11-167; 11-169). As mentioned previously, at times thalamoperforating branches and the medial posterior choroidal artery arise from the postcommunical part.

**Fig. 11-169.** Vertebral arteriogram showing both posterior and anterior projections of the posterior cerebral artery (pca), as well as other vessels derived from the vertebral artery that supply the brain stem, cerebellum, and spinal cord. As, Anterior spinal artery; b, basilar artery; lc, lateral posterior choroidal artery; mc, medial posterior choroidal artery; pc, posterior communicating artery; pica, posterior inferior cerebellar artery; pm, posterior meningeal artery; pp, posterior pericallosal artery; sc, superior cerebellar artery; tpa, thalamoperforating arteries; v, vertebral artery. (From M. M. Schechter, in *Neurological Surgery*, Vol. 1, edited by J. R. Youmans, W. B. Saunders, Philadelphia, 1982.)

**Peduncular and lateral posterior choroidal arteries** nearly always arise from the postcommunical part of the posterior cerebral artery (Fig. 11-169). Just beyond the junction of the posterior communicating artery near the lateral aspect of the base of the cerebral peduncles, the peduncular arteries branch from the posterior cerebral artery. These course dorsally and somewhat laterally to help supply the parahippocampal gyrus and the inferomedial cortex of the temporal lobe. Other branches arise that supply the lateral geniculate body, the pulvinar, the dentate gyrus, and the hippocampus (Krayenbühl and Yaşargil, 1968). One or two lateral posterior choroidal arteries arise from the ventrolateral aspect of the posterior cerebral trunk, become directed around the brain stem, enter the choroid fissure, and with branches of the anterior choroidal artery, help supply the choroid plexus in the inferior horn of the lateral ventricle. The lateral posterior choroidal arteries also send prominent branches to the thalamus.

**TERMINAL PART.** The terminal part or cortical segment of the posterior cerebral artery commences on the dorsolateral aspect of the brain stem, dorsal to the edge of the tentorium and caudal to the lateral geniculate bodies. At this point, the posterior cerebral artery usually divides into several cortical branches. In some descriptions, these vessels are called the anterior temporal, posterior temporal, parieto-occipital and occipital (or calcarine) arteries (see Chapter 8). The terminology adopted by the *Nomina Anatomica* (1977) subdivides the terminal part of the posterior cerebral artery into lateral and medial occipital arteries. According to this classification, the smaller **lateral occipital artery** divides into **anterior**, **intermediate**, and **posterior temporal branches**, which supply the inferomedial and inferolateral aspects of the temporal and occipital lobes, including the uncus, parahippocampal gyrus, and the more rostral parts of the medial and lateral occipitotemporal gyri, as well as the inferior temporal gyrus (Fig. 11-170). The larger **medial occipital artery** divides into a **dorsal callosal branch** and **parietal**, **parieto-occipital**, **calcarine**, and **occipitotemporal branches** (Fig. 11-173). The dorsal callosal and parieto-occipital branches supply the isthmus of the cingulate gyrus, the splenium of the corpus callosum, and the cortex of the cuneus and lingual gyrus. The

**FIG. 11-170.** The medial surface of the posterior part of the cerebral hemisphere, indicating the regions supplied by different vessels from the vertebrobasilar arterial system. Note that the posterior cerebral artery, which includes its posterior choroidal branches (vertically hatched zone 1), supplies the posterior part of the diencephalon and telencephalon. (From H. Krayenbühl and M. G. Yaşargil, in *Handbook of Clinical Neurology*, Vol. 11, edited by J. P. Vinken and G. W. Bruyn, American Elsevier, New York, 1972.)

parietal, parieto-occipital, and calcarine branches supply the medial surface of the occipital lobes from the lingual gyrus through the cuneus to the parieto-occipital sulcus, including the occipital pole (Fig. 11-173).

### Posterior Communicating Artery

The posterior communicating artery is approximately 1.5 cm long. It interconnects the posterior cerebral and internal carotid arteries and thereby participates in the formation of the *circulus arteriosus cerebri* (Fig. 11-167). It is generally smaller in diameter than the posterior cerebral artery, but it varies in size in different individuals and, rarely, it may be absent or doubled. More often than not, the two posterior communicating arteries in the same individual are

about equal in caliber. The posterior communicating artery provides an anastomosis between the internal carotid and vertebrobasilar circulations and also an arterial link between the two cerebral hemispheres.

The posterior communicating artery usually supplies an **oculomotor nerve ramus** in its course dorsal and medial to that nerve. Near its internal carotid junction it also sends several **rami to the optic chiasma**, while more caudally small **hypothalamic branches** course to the neural tissue that forms the wall of the third ventricle, and **thalamic branches** supply the medial thalamic region. Frequently, another ramus, the **branch to the tail of the caudate nucleus**, supplies that structure as well as the posterior limb of the internal capsule.

#### Anterior Choroidal Artery

The anterior choroidal artery is a small (0.6 to 1.0 mm in diameter) but important branch of the internal carotid artery; it arises usually 2 to 4 mm distal to the posterior communicating-internal carotid junction (Fig. 11-167). Absence of this vessel is rare. From its origin lateral to the optic chiasma, the anterior choroidal artery courses posteriorly and assumes a position along the medial border of the optic tract, which it follows as far as the rostral margin of the lateral geniculate body. The artery then passes laterally toward the medial surface of the temporal lobe, and coursing around the uncus, enters the tip of the temporal (inferior) horn of the lateral ventricle through the choroidal fissure.

The number and size of the branches of the anterior choroidal artery vary considerably, and thus, its region of distribution also varies somewhat. Branches to the following structures and regions, however, are frequently observed and have been described (Goldberg, 1974): (1) perforating branches to the caudal two-thirds of the optic tract, which continue through the *anterior perforated substance* to terminate in the lateral and medial segments of the *globus pallidus* and the *genu of the internal capsule*; (2) laterally directed branches to the *piriform cortex* and *uncus* of the temporal lobe with perforating branches to the underlying *amygdaloid body*, the anterior part of the *hippocampal formation*, and the *tail of the caudate nucleus*; (3) medially directed branches to the *cerebral peduncle*, some of which course more deeply to the *substantia*

*nigra* and *red nucleus* in the rostral midbrain and subthalamus and to nuclei in the ventral part of the *thalamus*; (4) distal branches that arise at the level of the *lateral geniculate body*, helping to supply it as well as the *posterior limb* and the *retrolenticular regions of the internal capsule*; these branches anastomose with rami from the lateral posterior choroidal branch of the posterior cerebral artery; and (5) branches to the *choroid plexus in the temporal (inferior) horn of the lateral ventricle*, which also anastomose with vessels from the lateral posterior choroidal artery.

#### Middle Cerebral Artery

The middle cerebral artery commences with the division of the internal carotid artery into its anterior cerebral and middle

**Fig. 11-171.** Photograph of the ventral surface of the right cerebral hemisphere in which the tip of the temporal lobe has been resected. Note the sphenoid or horizontal part of the middle cerebral artery (open arrows) coursing laterally from its origin at the internal carotid artery to the site at which it enters the lateral sulcus (double solid black arrow). The lateral frontobasal (orbitofrontal) branch (solid black arrow), coursing to the inferior surface of the frontal lobe, and the anterior temporal branch (solid white arrows) looping laterally and backward to the temporal lobe arise from the middle cerebral just proximal to its entrance into the lateral sulcus. (From B. A. Ring, in *Radiology of the Skull and Brain: Angiography*, edited by T. H. Newton and D. G. Potts, Vol. 2, Book 2, C. V. Mosby Co., St. Louis, 1974.)

cerebral branches (Figs. 11-167; 11-171). Although the middle cerebral artery is considered the largest branch of the internal carotid artery, for all practical purposes it appears as the lateral continuation of the internal carotid along the base of the brain above the lesser wing of the sphenoid bone. This initial horizontal segment is called the **sphenoid part** of the middle cerebral artery and it averages 1.5 cm in length. Its course laterally crosses the inferior surface of the anterior perforated substance and this places it almost immediately between the temporal lobe and the apex of the insula (Fig. 11-171). As it enters the lateral cerebral sulcus at the limen insulae, the **insular part** of the middle cerebral artery turns dorsally and caudally and quickly divides into two (90% of cases) or three (10% of cases) branches. Continuing upward and backward within the depth of the lateral cerebral sulcus, the cortical or **terminal part** of the middle cerebral artery gives rise to many branches that emerge from the lateral cerebral sulcus and course anteriorly, superiorly,

and posteriorly to supply the lateral surface of most of the frontal lobe, nearly all of the parietal lobe, and most of the temporal lobe (Fig. 11-172).

**SPHENOID PART.** The sphenoid part of the middle cerebral artery gives rise only to **anterolateral central arteries** and generally does not supply any part of the cerebral cortex. Occasionally, however, it does give rise to the **medial frontobasal artery** (medial orbitofrontal artery), but usually this vessel arises from the anterior cerebral artery (Fig. 11-173). The anterolateral central arteries are also known as the *anterolateral thalamostriate arteries* or the *lenticulostriate arteries* and consist of 10 to 15 delicate vessels that are divided into medial and lateral groups (Fig. 11-167).

The **medial striate arteries** arise from the proximal part of the middle cerebral artery, perforate the medial part of the anterior perforated substance, and supply both segments of the globus pallidus, the caudate nucleus, the internal capsule, and perhaps, even the lateral aspect of the thalamus. The **lateral**

**FIG. 11-172.** Arteries on the superolateral aspect of the cerebral cortex (lateral view). Cortical branches of the middle cerebral artery are shown in red; anterior cerebral artery, in yellow; posterior cerebral artery, in green.

**FIG. 11-173.** Arteries on the medial surface of the cerebral hemisphere. Branches of the middle cerebral artery are shown in red; anterior cerebral artery, in yellow; posterior cerebral artery, in green.

**striate arteries** arise from the middle cerebral artery just distal to the origins of the medial striate vessels. They penetrate the lateral part of the anterior perforated substance to supply the putamen, the internal capsule, and the caudate nucleus.

**INSULAR PART.** From the insular part of the middle cerebral artery arise insular, lateral frontobasal (lateral orbitofrontal), and anterior, intermediate, and posterior temporal arteries. Penetrating branches of the **insular arteries** (also called operculofrontal arteries) supply the limen insulae, the gyri brevi, and the gyrus longus, which form the insular lobe. These also penetrate more deeply to supply the extreme and external capsules and the claustrum. As the sphenoid part of the middle cerebral artery approaches the limen insulae, it already has bifurcated or trifurcated. These two or three branches give rise to a group of five to eight vessels that ascends in the lateral cerebral sulcus and then courses laterally over the surface of the insula as insular arteries. Because these vessels branch symmetrically in a fan-like manner and are visible as such in an angiogram, the term *candelabrum* is frequently used to identify them as a group.

After supplying the insula, these arteries follow the curvatures of the opercula to emerge from the lateral cerebral sulcus and continue their ascent over the lateral surface of the frontal and parietal lobes.

The **lateral frontobasal artery** (lateral orbitofrontal artery) arises from the middle cerebral artery just beyond the origins of the lateral striate arteries (Figs. 11-171; 11-172; 11-174). It almost immediately emerges from the lateral cerebral sulcus and courses anteriorly to supply the inferolateral and lateral orbital surfaces of the frontal lobe.

The anterior, intermediate, and posterior temporal arteries also emerge from the lateral cerebral sulcus and then course posteriorly and inferiorly to supply the lateral surface of the temporal lobe (Figs. 11-172; 11-174). Of these latter vessels, the **anterior temporal artery** arises from the middle cerebral artery most proximally and at about the same level as the lateral frontobasal artery. Near its origin, it emerges immediately from the lateral cerebral sulcus, loops over the posterior bank of that sulcus, courses inferiorly over the temporal lobe, and becomes distributed to the anterior third of the superior, middle, and inferior temporal gyri.

Most of the time a branch of the anterior temporal artery called the *temporal polar artery* passes forward to supply the tip of the temporal lobe (Figs. 11-172; 11-174).

The **intermediate temporal artery** arises from the middle cerebral artery at about the level of the pars opercularis of the inferior frontal gyrus. It is frequently quite small, and it quickly leaves the lateral cerebral sulcus and curves backward over the margin of the superior temporal gyrus to supply the superior and middle temporal gyri behind the cortical field served by the anterior temporal artery (Fig. 11-174).

The **posterior temporal artery** arises from the posterior trunk of the middle cerebral artery if a bifurcated or trifurcated middle cerebral pattern exists (Michotey, Moscow and Salamon, 1974). It emerges from the lateral cerebral sulcus at a point just below the postcentral gyrus and courses in an oblique posteroinferior direction over the temporal lobe. The posterior temporal artery supplies the middle and posterior parts of the superior temporal gyrus and the more posterior portions of the middle and inferior temporal gyri (Fig. 11-174).

**TERMINAL PART.** The terminal part of the middle cerebral artery gives rise to a group of ascending vessels that emerge from the lateral cerebral sulcus and course over its anterosuperior bank to supply the superior and lateral surfaces of the frontal and parietal lobes. These vessels include the prefrontal, precentral, central, anterior and posterior parietal, and angular arteries (Fig. 11-172).

The **prefrontal artery** leaves the lateral cerebral sulcus adjacent to the pars orbitalis of the inferior frontal gyrus and courses anterosuperiorly over the rostral part of the inferior, middle, and superior frontal gyri (Figs. 11-172). It supplies the anterolateral aspect of the frontal lobe in front of the precentral sulcus (Fig. 11-175), partly overlapping the fields of the lateral frontobasal artery below and that of the precentral artery behind. The **precentral artery** arises from the anterior trunk of the middle cerebral artery if the middle cerebral artery is bifurcated. It crosses the insula and then curves backward to emerge from the lateral cerebral sulcus at the level of the pars orbitalis of the inferior frontal gyrus, in close proximity to the prefrontal artery (Fig. 11-172). Its main trunk usually ascends on the lateral surface of the cerebral cortex within

**Fig. 11-174.** Cortical fields of distribution of the lateral frontobasal (A), posterior temporal (B), intermediate temporal (C), an anterior temporal with temporal polar (D) branches of the middle cerebral artery. (Modified from Michotey, Moscow, and Salamon, 1974.)

the precentral sulcus and branches course forward to supply the posterior parts of the superior, middle, and inferior frontal gyri and backward to supply the precentral gyrus (Fig. 11-175). It partially overlaps the field of the prefrontal artery anteriorly and that of the central artery posteriorly.

**FIG. 11-175.** Cortical fields of distribution of the prefrontal (A), precentral (B), central (C), and anterior and posterior parietal (D) branches of the middle cerebral artery. (Modified from Michotey, Moscow, and Salamon, 1974.)

The **central artery** arises from the anterior trunk of a bifurcated middle cerebral artery or the middle trunk of a trifurcated vessel. If the middle cerebral artery remains a single vessel, the central artery may arise from a common branch with the anterior parietal artery (Michotey, Moscow and Salamon, 1974). The central artery emerges from the

lateral cerebral sulcus just below the central sulcus (Fig. 11-172). It ascends on the lateral surface of the cerebral cortex within the central sulcus, and it sends branches to both the anterior and posterior banks of the central sulcus to supply the upper part of the precentral gyrus and the lower two-thirds of the postcentral gyrus (Fig. 11-175). Posteriorly it overlaps part of the field supplied by the postcentral and anterior parietal arteries, and anteriorly it supplies the region of the precentral gyrus not reached by the precentral artery. The **postcentral artery** courses along the postcentral sulcus.

The **anterior and posterior parietal arteries** arise near the summit of the lateral cerebral sulcus and ascend over the inferior and superior parietal lobules on the lateral surface of the parietal lobe, branching as far backward as the parieto-occipital sulcus (Fig. 11-172). The anterior parietal artery partially supplies the postcentral gyrus and the anterior parts of the inferior and superior parietal lobules. The posterior parietal artery supplies the supramarginal gyrus and the posterior parts of the two parietal lobules. Its field does not generally extend into the occipital lobe (Fig. 11-175).

The angular and temporo-occipital arteries emerge from the lateral cerebral sulcus opposite the supramarginal gyrus (Fig. 11-172). The **angular artery** is often the largest of the branches of the middle cerebral artery, and it courses posteriorly to supply the supramarginal and angular gyri and the lateral surface of the occipital lobe below the parieto-occipital sulcus and above the occipital pole. It also helps to supply the posterior part of the superior temporal gyrus (Fig. 11-176). The **temporo-occipital artery** courses posteroinferiorly from the lateral

**FIG. 11-176.** The cortical field of distribution of the angular branch of the middle cerebral artery. (Modified from Michotey, Moscow, and Salamon, 1974.)

**Fig. 11-177.** The cortical field of distribution of the temporo-occipital branch of the middle cerebral artery. (Modified from Michotey, Moscow, and Salamon, 1974.)

cerebral sulcus, and it may arise as an individual vessel from the middle cerebral artery or from a common stem with the angular artery (Fig. 11-172). It supplies the posterior portions of the temporal gyri and the inferolateral surface of the occipital lobe, but it does not extend as far as the occipital pole (Fig. 11-177). The angular and temporo-occipital arteries supply the lateral cerebral surfaces of areas 18 and 19, but not the striate cortex of area 17. The latter area is served by the posterior cerebral artery.

### Anterior Cerebral Artery

When the internal carotid arteries enter the cranial cavity on each side at the base of the brain, they are located on the medial aspect of the lateral cerebral sulcus. Each internal carotid artery terminates by bifurcating into the anterior and middle cerebral arteries, of which the smaller is the anterior cerebral artery (Fig. 11-167). From its origin, the anterior cerebral artery courses medially and slightly anteriorly across the base of the brain, dorsal to the optic nerve and just in front of the optic chiasma (Fig. 11-178). Upon reaching the longitudinal cerebral fissure that separates the cerebral hemispheres, the two anterior cerebral arteries are joined across the midline by the **anterior communicating artery** (Fig. 11-178). Beyond the anterior communicating artery, the two anterior cerebral arteries ascend side by side in the longitudinal cerebral fissure, just in front of the lamina terminalis. Each vessel then passes along the medial surface of its respective hemisphere by curving upward and backward around the genu of the corpus cal-

losum (Figs. 11-173; 11-179). The principal trunk of the anterior cerebral artery continues backward along the upper surface of the corpus callosum, extending nearly to the splenium. During its course, several vessels branch from the principal stem to ramify along the medial surface of the cerebrum and thereby help to supply the frontal and parietal lobes (Fig. 11-173). The portion of the anterior cerebral artery that extends from the internal carotid bifurcation to the anterior communicating artery (about 1.5 cm in length) is called the **precommunical part** (proximal segment or horizontal part), while beyond the anterior communicating artery, the main trunk of the anterior cerebral artery is referred to as the **postcommunical part** (or pericallosal part).

**PRECOMMUNICAL PART.** The precommunical part of the anterior cerebral artery supplies a number of central arteries that penetrate the base of the brain along the horizontal course of the vessel from the in-

**Fig. 11-178.** Photograph of the base of the brain, showing the precommunical part of the anterior cerebral artery and the anterior communicating artery (arrow). (From J. P. Lin and I. I. Kricheff, in *Radiology of the Skull and Brain: Angiography*, Vol. 2, Book 2, edited by T. H. Newton and D. G. Potts, C. V. Mosby, St. Louis, 1974.)

ternal carotid bifurcation to the anterior communicating artery. These include the anteromedial central arteries (anteromedial thalamostriate arteries) that come directly from the anterior cerebral and the central anteromedial rami of the anterior communicating artery.

The **anteromedial central arteries** are usually divided into short central arteries, of which there are both medial and lateral perforators, and the long central artery (also called the recurrent artery of Heubner<sup>1</sup>). The **short medial and lateral central arteries** arise from both the dorsal and ventral aspects of the precommunical part. Those arising ventrally supply the superior surface of the optic nerve and optic chiasma. From the dorsal aspect of the precommunical part of the anterior cerebral artery arise 8 to 12 more laterally located short perforating central arteries and anywhere from 4 to 10 more medially located perforators. All of these vessels penetrate the ventral aspect of the basal forebrain, with some entering the anterior perforated substance and others, the olfactory trigone and olfactory striae to achieve deeper forebrain structures. They supply the preoptic region and the anterior hypothalamus caudally to the infundibulum, the genu of the corpus callosum, the septal region and anterior commissure, the fornix and the anteroinferior aspect of the striatum. The **long central artery** (recurrent artery of Heubner) originates medially near the anterior communicating artery and it then courses laterally for about 2 or 3 cm before ascending and entering the anterior perforated substance, just medial to the short central arteries (Fig. 11-167). It may send a branch anteriorly to supply part of the medial aspect of the orbital surface of the frontal lobe and olfactory bulb. Its principal region of supply is the anterior limb of the internal capsule, the anterior and medial aspects of the head of the caudate nucleus, and the anterior parts of the putamen and globus pallidus.

**ANTERIOR COMMUNICATING ARTERY.** The anterior communicating artery is a short vessel (0.1 to 3.0 mm long) that interconnects the two anterior cerebral arteries across the longitudinal cerebral fissure and forms the rostral part of the cerebral arterial circle of

Willis (Figs. 11-167; 11-178). This artery has a variable pattern, and it may be doubled, Y-shaped, reticulated, very short and thick, or quite slender and long. Several small perforating **central anteromedial rami** arise from the anterior communicating artery and supply the optic chiasma, the preoptic region, and the hypothalamus in the region of the infundibulum. In about 10% of specimens, a vessel called the **anterior middle cerebral artery** (median artery of the corpus callosum) arises from the anterior communicating artery and ascends over the corpus callosum in the midline to supply—in addition to the rostrum, genu, and anterior part of the trunk of the corpus callosum—the septal nuclei, the septum pellucidum, and the fornix. In certain cases when the anterior cerebral artery is absent or hypoplastic, the anterior middle cerebral artery has large branches that supply cortical areas normally served by the anterior cerebral artery.

**POSTCOMMUNICAL PART.** The postcommunical part of the anterior cerebral artery (also called the pericallosal segment or artery) is the portion of the anterior cerebral artery distal to the anterior communicating artery. Ascending around the genu of the corpus callosum, it continues posteriorly above the corpus callosum to supply the medial surface of the cerebral hemisphere (Figs. 11-173; 11-179). Its branches include the medial frontobasal artery, the frontopolar artery, the callosomarginal artery, and the paracentral, precuneal, and parieto-occipital artery.

The **medial frontobasal artery** (also called the medial orbitofrontal artery) arises several millimeters distal to the anterior communicating artery as the first important branch of the postcommunical part of the anterior cerebral artery. It courses anteriorly along either the inferior part of the medial surface of the frontal lobe or the medial aspect of the orbital surface and it supplies the gyrus rectus and the region of the olfactory tract as far as the olfactory bulb (Figs. 11-173; 11-179). The **frontopolar artery** arises from the main stem of the anterior cerebral artery at about the level of the genu of the corpus callosum. At times a single branch arises from the anterior cerebral artery, which then divides into the medial frontobasal artery and the frontopolar artery. From its origin the frontopolar artery (sometimes doubled) courses anteriorly in a gradual curve along

**Fig. 11-179.** The anterior cerebral artery and its branches along the medial surface of the cerebral hemisphere. The numbered branches are (1) short medial and lateral central arteries and the long central artery (recurrent of Heubner); (2) anterior middle central artery (actually from the anterior communicating artery); (3) medial frontobasal artery; (4) frontopolar artery; (5a and 5b) callosomarginal artery and its anteromedial, intermediodorsal, and posteromedial frontal rami and the cingular ramus; (6) pericallosal artery (continuation of the anterior cerebral trunk; also called artery of the corpus callosum); (7) paracentral, precuneal, and parieto-occipital terminal branches. (From H. Krayenbühl and M. G. Yaşargil, in *Handbook of Clinical Neurology*, Vol. 11, edited by J. P. Vinken and G. W. Bruyn, American Elsevier, New York, 1972.)

the medial surface of the frontal lobe toward the frontal pole (Figs. 11-173; 11-179). It supplies the anterior part of the medial frontal gyrus and it extends over the superior border of the cerebrum to supply the anterior part of the superior frontal gyrus on its superolateral surface.

Several centimeters beyond the origin of the frontopolar artery, the main stem of the anterior cerebral artery gives off a large branch called the **callosomarginal artery** (Figs. 11-173; 11-179). Arising near the summit of the genu of the corpus callosum, the callosomarginal artery courses along the medial surface of the cerebrum over the cingulate gyrus. Its path along the cingulate sulcus is nearly parallel to the main trunk of the anterior cerebral artery, which lies in the sulcus of the corpus callosum. From the callosomarginal artery arise **anteromedial**, **intermediodorsal**, and **posteromedial frontal rami**, as well as a **cingular ramus**; these supply the medial surface of the posterior part of the frontal lobe and the rostral part of

the parietal lobe, as well as part of the cingulate gyrus (Figs. 11-173; 11-179).

Continuing caudally, the main stem of the anterior cerebral artery branches into terminal vessels called the **paracentral**, **precuneal**, and **parieto-occipital arteries** (Figs. 11-173; 11-179). These arteries supply the more caudal part of the medial surface of the parietal lobe, including the paracentral lobule and the precuneus, and their vascular fields extend caudally to the parieto-occipital sulcus.

### **Meninges of the Brain and Spinal Cord**

The brain and spinal cord are enclosed by three membranes: (1) an outer tough, protective membrane, the **dura mater**, (2) a subjacent delicate, spider web-like structure called the **arachnoid mater**, and (3) an inner, finely structured fibrous membrane that carries blood vessels to the brain and spinal cord called the **pia mater**. The dura mater is also frequently called the **pachymeninx**, while the arachnoid and pia mater are collectively called the **leptomeninges**.

**DURA MATER**

The dura mater is a thick, dense, and tough, inelastic membrane composed of fibrous connective tissue with collagenous bundles arranged in interlacing layers. The portion of the dura mater that encloses the brain, the **dura mater encephali**, differs in several essential particulars from that which surrounds the spinal cord, the **dura mater spinalis**, and therefore it is necessary to describe them separately. It must be emphasized, however, that these two regional parts of the dura mater form one complete membrane and are continuous with each other through the foramen magnum.

**Cranial Dura Mater (Dura Mater Encephali)**

The cranial dura mater serves as both an internal periosteum for the bones that encase the cranial cavity and a membrane for the protection of the brain. It may be considered to consist of two layers: an outer or **endosteal layer** and an inner or **meningeal layer**. These two layers are tightly fused except in certain places where they are separated to provide space for the venous sinuses, within which venous blood drains from the cranial cavity. The outer surface of the dura mater is rough and fibrillated, and it adheres closely to the inner surface of the cranial bones. It sends many fine fibrous and vascular projections into the bony substance; these are severed when the dura is stripped from the bones. Because the adhesions are most marked along the sutures and at the base of the skull, the dural attachments are most secure at these sites. The internal surface of the dura is smooth, unattached, and covered with a layer of squamous mesothelial cells that line the subdural space.

The outer or endosteal layer is continuous through the suture lines and the foramina at the base of the skull with the pericranium that lines the external surface of the cranial bones. The inner meningeal layer (a) separates from the endosteal layer to form the venous sinuses (described in Chapter 9); (b) forms a sheath that surrounds the cranial nerves through their sites of exit at the foramina in the base of the skull; (c) sends inwardly three partitions, called the falx cerebri, the tentorium cerebelli, and the falx

cerebelli, which separate large divisions of the brain; (d) forms a roof for the sella turcica, called the diaphragma sellae, which overlies the hypophysis; and (e) forms the cavum trigeminale, which lodges the trigeminal ganglion.

**FALX CEREBRI.** The falx cerebri, named because of its sickle-like shape, is a strong, arched membrane that extends vertically downward in the longitudinal fissure between the two cerebral hemispheres (Fig. 11-180). It is narrow anteriorly, where it is attached to the crista galli of the ethmoid bone, and broad posteriorly, where it is continuous with the tentorium cerebelli. Its upper margin is convex and attached superiorly to the inner surface of the cranial vault in the midline as far back as the internal occipital protuberance. At this attachment it is separated from the outer layer of dura, leaving space for the superior sagittal sinus (Fig. 11-180). The free inferior margin is concave, and overlying the corpus callosum, it contains the inferior sagittal sinus. Posteriorly, the inferior border of the falx cerebri attaches to the tentorium cerebelli. Along this attachment is the straight sinus (Figs. 11-180; 11-181).

**TENTORIUM CEREBELLI.** The tentorium cerebelli is a transversely oriented semilunar fold of dura mater that covers the superior surface of the cerebellum and underlies the occipital lobes of the cerebrum (Figs. 11-180; 11-181). Because the upper surface of the cerebellum is convex, the center of the tentorium is much higher than its sides. Its anterior border is free and sharply concave and it bounds a large oval opening called the **tentorial incisure**, which surrounds the midbrain and through which the posterior cerebral arteries pass in their supratentorial course to the cerebral hemispheres.

The outer, broad, and convex border of the tentorium cerebelli attaches posterolaterally to the edges of the sulcus for the transverse sinus on the inner surface of the occipital bone; thus, it encloses the transverse sinuses (Fig. 11-181). Anterolaterally, it is attached along the superior margin of the petrous part of the temporal bone and encloses the superior petrosal sinus on both sides. Anteromedially, near the apex of the petrous part of the temporal bone, the free and attached borders of the tentorium cerebelli meet and cross each other. The free border passes above and is fixed to the anterior

**Fig. 11-180.** The cerebral dura mater and the dural sinuses, seen after removal of the left side of the skull and the brain. Note the cerebral falx and the tentorium cerebelli. (After Sobotta.)

clinoid process of the sphenoid bone, while the attached border passes below to become anchored to the posterior clinoid process of the same bone. The posterior portion of the inferior border of the falx cerebri attaches to the upper surface of the tentorium cerebelli along the midline, thereby enclosing the straight sinus.

**FALX CEREBELLI.** The falx cerebelli is a small sickle-shaped, somewhat triangular fold of dura mater located between the hemispheres of the cerebellum. Its base is attached in the median plane above to the inferior and posterior parts of the tentorium. It has a free anterior border that projects forward into the posterior cerebellar notch be-

tween the cerebellar hemispheres. Its posterior border, which contains the occipital sinus, is attached along the vertically oriented internal occipital crest on the inner surface of the occipital bone, thereby incompletely dividing the posterior cranial fossa into two halves.

**DIAPHRAGMA SELLAE.** The diaphragma sellae is a small, circular, horizontal fold of dura mater that attaches to the clinoid processes and forms a roof for the sella turcica, which contains the hypophysis (Fig. 11-181). A circular opening in the center transmits the infundibulum of the hypothalamus, which is surrounded by the intercavernous sinus (Fig. 11-180). Partially covering the

**Fig. 11-181.** The tentorium cerebelli, viewed from above with the brain removed. Observe that its anterior free margin bounds an oval opening called the tentorial incisura. The transverse sinus (which continues as the sigmoid sinus) lies in the posterolateral attached margin of the tentorium.

dorsal surface of the diaphragma sellae is the optic chiasma.

**CAVUM TRIGEMINALE.** The cavum trigeminale (trigeminal cave of Meckel<sup>1</sup>) is a cleft-like recess located between the endosteal and meningeal dural layers in the middle cranial fossa near the apex of the petrous portion of the temporal bone, just below the superior petrosal sinus. It lodges the posterior part of the trigeminal ganglion and the roots of the trigeminal nerve, and it is fused anteriorly with the dura that forms the lateral wall of the cavernous sinus.

**STRUCTURE OF THE DURA MATER.** The dura mater is formed chiefly of dense fibrous connective tissue, mixed with some elastic fibers, and as its name suggests, it has a tough consistency. Its connective tissue fibers are arranged in flattened laminae that are incompletely separated into two layers, endosteal

and meningeal. The **endosteal layer** is the internal periosteum for the cranial bones, and it contains the blood vessels for their supply. At the margin of the foramen magnum, the endosteal layer of the cranial dura mater is continuous with the periosteum lining the vertebral canal. The **meningeal layer** overlies the arachnoid, and it is lined on its inner surface with a flattened, nucleated layer of cells that appears to be mesothelial and similar to that found lining serous membranes.

**ARTERIES AND VEINS OF THE DURA MATER.** The **arteries** that course within the dura mater are numerous and derived from several sources; they principally supply the cranial bones. Those in the *anterior fossa* are the anterior meningeal branches of the anterior and posterior ethmoidal arteries and of the internal carotid artery, as well as a branch from the middle meningeal artery. The vessels that supply the dura mater in the *middle fossa* are the middle and accessory meningeal branches of the maxillary artery; the meningeal branch of the ascending pharyngeal artery, which enters the skull through the foramen lacerum; branches from the internal carotid artery; and the recurrent meningeal branch of the lacrimal artery. Arteries that supply the dura mater

<sup>1</sup>Johann Friedrich Meckel (1714-1774): German anatomist, gynecologist, and botanist (Berlin).

in the *posterior fossa* include two meningeal branches from the occipital artery, one that enters the skull through the jugular foramen and another that enters through the mastoid foramen; the posterior meningeal branches from the vertebral artery; other meningeal branches from the ascending pharyngeal artery that enter the skull through the jugular foramen and hypoglossal canal; and a branch from the middle meningeal artery.

The **veins** returning blood from the cranial dura mater anastomose with the diploic veins and end in the various sinuses. Many of the meningeal veins do not open directly into the sinuses, but indirectly through a series of ampullae termed **venous lacunae**. These are found on either side of the superior sagittal sinus, especially near its middle portion, and are often invaginated by the arachnoid granulations. Venous lacunae are also found near the transverse and straight sinuses. The veins in the dura mater communicate with the underlying cerebral veins, as well as with the diploic and emissary veins.

**NERVES OF THE DURA MATER.** The cranial dura mater is richly supplied by sensory nerve fibers and sympathetic fibers; most of the latter course to the dural vessels. The sensory fibers are derived from the trigeminal ganglion, from each of the three divisions of the trigeminal nerve, as well as from the upper two or three cervical segments. The latter appear both to course with the vagus and hypoglossal nerves and to ascend directly through the foramen magnum to supply the dura mater of the posterior fossa. Sympathetic fibers to the dural vessels course along the arteries from the vertebral and carotid sympathetic plexuses.

### Spinal Dura Mater (Dura Mater Spinalis)

The spinal dura mater forms a loose sheath around the spinal cord and represents only the inner or meningeal layer of the cranial dura mater (Fig. 11-182). The outer or periosteal layer of the cranial dura mater becomes the periosteum of the vertebrae below the foramen magnum and forms the lining of the vertebral canal. A considerable interval, the **epidural cavity**, intervenes between the spinal dura and the periosteal lining of the vertebral canal. It contains a quantity of loose areolar tissue and a plexus of veins that corresponds in position with the cranial dural sinuses. The spinal dura is attached to the circumference of the foramen magnum, to the second and third cervical vertebrae, and by fibrous slips to the posterior longitudinal ligament, especially near the caudal end of the vertebral canal.

The substance of the spinal cord diminishes significantly caudal to the second lum-

bar vertebra and the cord ends at this level in a conical extremity called the **conus medullaris**. From the apex of the conus medullaris, a delicate fibrous filament called the **filum terminale** descends for about 20 cm as far as the first coccygeal vertebral segment (Figs. 11-26; 11-27). Between the second lumbar vertebra and the level of the second sacral vertebra, the conus medullaris and filum terminale are surrounded by the longitudinally oriented roots of the spinal nerves that course intradurally. This portion of the cord is called the **cauda equina** and it is surrounded by spinal dura mater. Below the second sacral vertebral level, the dura mater closely invests the final 5 cm of the filum terminale (filum terminale externum) and attaches caudally to the dorsum of the first coccygeal vertebra by blending with the periosteum (Fig. 11-27).

The intradural volumetric capacity is considerably greater than that required by the spinal cord and leptomeninges. Much of the additional space is occupied by cerebrospinal fluid located deep to the arachnoid membrane in the so-called subarachnoid space (Fig. 11-182). An especially spacious portion of the subarachnoid space exists deep to the dura mater and arachnoid membrane between the apex of the conus medullaris (third lumbar vertebra) and the second sacral vertebral level along the course of the upper 15 cm of the filum terminale (filum terminale internum). This is a convenient site for the sampling of cerebrospinal fluid (lumbar puncture) or the injection of anesthetics (spinal anesthesia).

Between the dura mater and the arachnoid membrane is found a potential space, called the **subdural space**, that contains a small amount of serous fluid (Fig. 11-182). The subdural space terminates at the lower border of the second sacral vertebra, where the filum terminale externum becomes invested closely by the dura mater. The dura mater forms tubular prolongations along both the roots of the spinal nerves and the proximal parts of the spinal nerves themselves as they pass through the intervertebral foramina on each side. These **dural sheaths** are short in the upper part of the vertebral column, but gradually they become longer in the lower part because of the greater interval that exists between the root-cord junction and the intervertebral foramina.

**Fig. 11-182.** Cross section of spinal cord in the spinal canal, showing its meningeal coverings and the manner of exit of the spinal nerves. (After Rauber in N. B. Everett, *Functional Neuroanatomy*, 6th ed., Lea & Febiger, Philadelphia, 1971.)

### THE ARACHNOID

The arachnoid (Figs. 11-182; 11-183; 11-185; 11-186) is a delicate, avascular membrane lying between the dura mater and pia mater. It is separated from the dura mater by the **subdural space** and from the pia mater by the **subarachnoid space**, which contains the cerebrospinal fluid. The arachnoid, together with the underlying pia mater, forms the **leptomeninges**. Although the pia and arachnoid are clearly different and separable membranes, fine trabecular strands extend inward to the pia mater from the arachnoid across the subarachnoid space (Fig. 11-185). This meshwork, along with the delicate texture of arachnoid tissue, gives a spider web-like appearance to the arachnoid mater, hence its name.

### Cranial Arachnoid

The cranial arachnoid is closely applied to the inner surface of the cranial dura but is separated from it by a thin film of fluid in the subdural space. Its surface adjacent to the dura is covered with a layer of mesothelium. It does not dip into the sulci or fissures except to follow the falx and tentorium. The inner surface of the arachnoid membrane attaches to the underlying pia mater by deli-

cate fibrous threads, the **arachnoid trabeculae**, which traverse the subarachnoid space intervening between these two membranes (Fig. 11-185).

### Spinal Arachnoid

The spinal arachnoid is a thin, delicate tubular sheath that loosely invests the spinal cord (Fig. 11-186). It is continuous above with the cranial arachnoid and it widens below to invest the cauda equina and its emerging nerves. Like the cranial arachnoid, the spinal arachnoid is separated from the spinal dura mater by the subdural space. As the cranial arachnoid surrounds the roots of the cranial nerves along their intracranial course between the foramina and the brain, so also the spinal arachnoid encloses the spinal nerves and forms loose sheaths that surround these nerves along their course within the vertebral canal between their sites of attachment to the spinal cord and their exits through the intervertebral foramina.

### SUBARACHNOID SPACE

The subarachnoid space is the cavity between the arachnoid and the pia mater (Figs. 11-182; 11-183). It contains cerebrospinal fluid located within intercommunicating

channels that are separated by delicate connective tissue trabeculae extending from the arachnoid to the pia. The inner surface of the arachnoid is lined by mesothelial-like cells that form a continuous layer over the trabeculae and likewise cover the outer surface of the pia mater. Because the subarachnoid space can be defined as a cavity that separates two parts of a continuous membrane, the *leptomeninges*, it may be considered an *intraleptomeningeal space*.

The subarachnoid space is narrow over the surface of the cerebral hemispheres and especially so over the summits of the cortical gyri, where the arachnoid and pia are in close contact. The arachnoid, however, bridges the sulci, whereas the pia follows the cortical surface closely and dips into the sulci. This results in a wider subarachnoid space along these intergyral sites. Over certain regions of the brain, the arachnoid is somewhat thicker and is separated from the pia mater by wide intervals that communicate freely with each other. These are called the **subarachnoid cisternae** and they contain little subarachnoid trabecular tissue (Fig. 11-183).

### Subarachnoid Cisternae

The subarachnoid cisternae are cavities of considerable size located within the subarachnoid space. They are found in regions where the arachnoid adheres closely to a loosely fitting meningeal dura mater that bridges the contours of the brain, while the pia mater remains intimately attached to the surface of the brain and follows its contours. Most of the cisternae are found adjacent to the ventral and dorsal surfaces of the brain stem and the ventral surface of the hypothalamus (Figs. 11-183; 11-184). Because they represent only enlargements within the common subarachnoid cavity, they contain cerebrospinal fluid. They have a clinical relevance because blood and exudates may accumulate at these sites, and certain cisternae may be punctured to obtain samples of their contents for analysis.

**CEREBELLOMEDULLARY CISTERN.** The cerebellomedullary cistern, often called the *cisterna magna*, is the largest and most accessible of the subarachnoid cisternae in the skull (Figs. 11-183; 11-184). It is found deep to the arachnoid that bridges the interval be-

tween the caudal part of the cerebellum and the dorsal surface of the medulla oblongata; the cerebellomedullary cistern is directly continuous below with the subarachnoid space of the spinal cord.

The ventricular system of the brain communicates with the subarachnoid space by way of three foramina. These open between the fourth ventricle and the cerebellomedullary cistern and include the **median aperture of the fourth ventricle** (foramen of Magendie), located in the midline at the inferior part of the roof of the fourth ventricle, and two **lateral apertures of the fourth ventricle** (foramina of Luschka), found at the extremities of the lateral recesses of the fourth ventricle between the flocculus of the cerebellum and the roots of the glossopharyngeal nerve (Fig. 11-183). Cerebellomedullary cisternal puncture is done by carefully introducing a needle through the posterior atlanto-occipital membrane and entering the cistern at the foramen magnum.

**PONTINE CISTERN.** The pontine cistern is a large space on the ventral aspect of the pons; within it courses the basilar artery longitudinally (Figs. 11-183; 11-184). It is continuous caudally with the subarachnoid space adjacent to the ventral surface of the medulla oblongata and spinal cord, and rostrally with the interpeduncular space.

**INTERPEDUNCULAR AND CHIASMATIC CISTERNAE.** The interpeduncular and chiasmatic cisternae are sometimes together called the *cisterna basalis* (Fig. 11-183). They are located rostral to the pontine cistern and adjacent to the ventral surfaces of the mesencephalon and hypothalamus. The optic chiasma separates the smaller, more rostrally located chiasmatic cistern from the wider and more extensive interpeduncular cistern. The interpeduncular cistern contains the *circulus arteriosus* and the posterior and middle cerebral arteries, while the chiasmatic cistern has coursing through it the anterior cerebral artery.

**CISTERNAE OF THE LATERAL CEREBRAL FOSSAE.** The cisternae of the lateral cerebral fossae, one on each side, are located at the base of the cerebrum, just medial to and in front of the temporal lobe. They are formed as the arachnoid membrane bridges the lateral sulci, and each contains the middle cerebral artery as that vessel courses toward and enters the lateral sulcus.

**Fig. 11-184.** A diagram showing the locations of the principal subarachnoid cisterns in the skull. Blue, arachnoid membrane; red, pia mater.

**CISTERN OF THE GREAT CEREBRAL VEIN.** The cistern of the great cerebral vein occupies the interval between the splenium of the corpus callosum, the pineal body, the superior surface of the cerebellum, and the colliculi of the mesencephalon (Figs. 11-183; 11-184). It reaches rostrally between the layers of the tela choroidea of the third ventricle, and through it courses the great cerebral vein (of Galen<sup>1</sup>).

As mentioned previously, the ventricular system of the brain communicates with the subarachnoid space by way of the median and lateral apertures of the fourth ventricle. The subarachnoid space surrounding the cerebral hemispheres and the intracranial cisternae are directly continuous with the subarachnoid space surrounding the spinal cord.

### Spinal Part of the Subarachnoid Space

The spinal part of the subarachnoid space is a relatively wide interval that is most spacious in the caudal part of the vertebral canal, where the arachnoid surrounds the lower roots of the spinal cord that form the cauda equina (Fig. 11-183). A longitudinally oriented **subarachnoid septum** incompletely divides the spinal subarachnoid space. This

septum connects the arachnoid to the pia mater along the posterior median sulcus of the cord; it is less complete in the upper cervical region but more definitive in the lower cervical and thoracic regions. On each side, the **denticulate ligaments** also tend to partition the spinal part of the subarachnoid space (see discussion on pia mater). The subarachnoid space ends at the level of the second sacral vertebra.

### Arachnoid Granulations

The arachnoid granulations (sometimes called the arachnoid villi or Pacchionian<sup>2</sup> bodies) are ovoid tufts of arachnoid tissue, visible to the naked eye, that protrude outward from the arachnoid membrane into the dura mater that forms the superior sagittal sinus, the transverse sinus, and at times certain other sinuses (Fig. 11-183). Each arachnoid granulation consists of a finger-like projection of arachnoid mesothelium that evaginates into the lumen of the sinus, so that the arachnoid mesothelium comes to lie adjacent to the vascular endothelium. The inner cavity of the granulation or villus is continuous with the subarachnoid space, and the cerebrospinal fluid within that space becomes separated from the venous blood only by the mesothelium of the arachnoid, which fuses with the endothelial lining of the sinus. Return of cerebrospinal fluid to the blood plasma is thought to be effected by osmosis across the mesothelial lining of the arachnoid villi and the vascular endothelium.

Although fully developed arachnoid granulations are not seen in the newborn infant and are rarely found before the third year, many minute elevations that will become arachnoid granulations can be seen quite early. They become obvious after the seventh year and they increase in number and size as age advances. During their growth, the arachnoid granulations push against the thinned dura and eventually cause absorption of bone; this results in the formation of ovoid pits or depressions on the inner table of the calvaria. The arachnoid granulations can readily be seen to occupy these depressions as the skull cap is removed during dissection of the adult cranial cavity.

### Cerebrospinal Fluid

The cerebrospinal fluid is a clear and colorless, watery liquid that fills the ventricles of the brain and occupies the subarachnoid space. It has a specific gravity of 1.006 to 1.009, and it normally contains 1.8 leukocytes/ml, some proteins, glucose, sodium, chloride, and lipids, as well as many other substances in small quantities. Although it may serve a nutritive role during development, cerebrospinal fluid probably functions in a protective capacity for the adult central nervous system. Because the brain and spinal cord are totally suspended in cerebrospinal fluid, they are buffered from the rigid bony skeleton of the skull and spinal column and are less subject to mechanical and concussive injury. Cerebrospinal fluid is constantly being formed by the choroid plexuses within the ventricles and it communicates with the subarachnoid space surrounding the brain and spinal cord. At any one time there may be as much as 140 ml of cerebrospinal fluid within and around the central nervous system, although it has been calculated that about 500 ml are formed daily, the excess being reabsorbed through the arachnoid villi into the venous system.

Cerebrospinal fluid circulates from its sites of formation in the lateral ventricles, through the interventricular foramina into the third ventricle, and then through the cerebral aqueduct into the fourth ventricle (Fig. 11-183). It passes into the cerebromedullary cistern (cisterna magna) and the pontine cistern by way of the medial and lateral apertures in the roof of the fourth ventricle and, thus, into the subarachnoid space. Within the subarachnoid space it continues to circulate around the surfaces of the cerebrum, cerebellum, and spinal cord and eventually it passes back into the venous circulation at the arachnoid granulations. Davson (1967) has estimated that of the 140 ml of cerebrospinal fluid present in the central nervous system at any one time, 23 ml are located within the ventricles, 30 ml are in the subarachnoid space of the spinal cord, and the rest is in the cerebral cisternae and the intracranial subarachnoid space.

As cerebrospinal fluid circulates in the subarachnoid space, it is interposed between the larger blood vessels and their penetrating branches on the one hand and the connective tissue of the pia mater on the other.

As the penetrating vessels divide to form capillaries, however, the pia mater is lost and the endothelial cells forming the capillary wall lie adjacent to the neuropil and are almost completely surrounded by the endfeet of astrocytic processes (Fig. 11-185). Because certain substances circulating in the blood stream, such as alcohol and glucose, quite freely enter the extracellular space or cerebrospinal fluid and come quickly to equilibrium, and other substances, such as proteins and certain vital dyes do not, a concept has developed that there exists a functional barrier between the blood and the brain that selectively allows the passage of some substances but restricts others. This physiologic mechanism has been called the **blood-brain** or **hematoencephalic barrier**. It is now thought that the tight junctions that interconnect the endothelial cells lining the capillaries in the central nervous system serve to limit the passage of certain substances across the capillary wall. This mechanism, in addition to others, may help to explain the blood-brain barrier phenomenon.

Obstruction of the flow of cerebrospinal fluid can cause an increased accumulation of intracranial cerebrospinal fluid, frequently characterized by an enlargement of the ventricles and an increased intracranial pressure. This condition is called **hydrocephalus**, and when it occurs before the closure of the fontanels of the skull of a child, the increase in intracranial pressure results in an enlargement of the head and, if severe enough, in the destruction of neural tissue. Because the skull is unable to expand in adults, obstruction of the passage of cerebrospinal fluid frequently results in ventricular dilatation. If flow is restricted through the cerebral aqueduct or through the medial and lateral apertures in the roof of the fourth ventricle, there results a noncommunicative obstruction because the passage of fluid between the ventricular system and the subarachnoid space is prevented. A communicating obstruction may occur somewhere in the subarachnoid space, such as in the cerebello-medullary or pontine cisternae.

**Lumbar puncture** is performed to sample spinal fluid that is circulating in the subarachnoid space surrounding the cauda equina of the spinal cord. A needle inserted in the midline between the spines of the third and fourth lumbar vertebrae will enter the sub-

**FIG. 11-185.** Diagrammatic representation of a portion of the subarachnoid space surrounding the cerebral cortex. Note the arachnoid trabeculae between the arachnoid membrane and the pia mater, and the fact that the subarachnoid space still exists around the vessels as they penetrate the neural substance. As these vessels branch into the capillary network of the brain, however, they lose their arachnoid covering and the connective tissue of the pia mater, while the neuroglia attach directly to the basement membrane of the endothelial cells. (From Benninghoff and Goertler, *Lehrbuch der Anatomie des Menschen*, Vol. 3, 9th ed., Urban and Schwarzenberg, Munich, 1975.)

arachnoid space, avoiding the spinal cord and insinuating itself among the nerves of the cauda equina (Fig. 11-27). **Cisternal puncture** is performed by inserting a needle between the atlas and the occipital bone and entering the cisterna cerebellomedullaris (cisterna magna). **Spinal anesthesia** is administered by introducing the anesthetic into the subarachnoid space by lumbar puncture.

#### PIA MATER

The innermost meningeal layer, the pia mater, is a delicate connective tissue and vascular membrane that closely adheres to the brain and spinal cord (Figs. 11-29; 11-185; 11-186). It carries a rich network of blood vessels that supply the neural tissue and it consists of loose interlacing bundles of collagenous and elastic fibers covered by a layer of flattened mesothelial-like squamous cells, similar to those seen in the arachnoid. The basement membrane on the innermost surface of the endothelial cells forming the

capillaries allows attachment of the astrocytic neuroglial processes, and together they form a **pia-glial membrane**. The astrocytes and their end-feet attachments make up a nearly complete sheath around the capillaries and may play an important role in the transfer of metabolic substances between the blood and the brain. On its external surface, the pia mater is attached to the overlying arachnoid by fine trabecular extensions of the arachnoid that cross the subarachnoid space (Fig. 11-185). The pia mater also forms sheaths for the cranial and spinal nerves and, together with the dura mater, blends with the perineurium as these nerves leave the cranial cavity and the vertebral canal. The pia mater and the arachnoid are often referred to collectively as the **leptomeninges**.

#### Cranial Pia Mater

The cranial pia mater invests the entire surface of the brain, dipping into the fissures and sulci of the cerebral and cerebellar

hemispheres (Fig. 11-185). It extends into the transverse cerebral fissure, where it forms the *tela choroidea* of the third ventricle and combines with the ependyma to form the choroid plexuses of the third and lateral ventricles. It also passes over the roof of the fourth ventricle and forms the *tela choroidea* and choroid plexus of the fourth ventricle.

Over the surface of the cerebrum, the pia mater contains the blood vessels that supply the brain, and from these vessels large numbers of branches arise that penetrate the brain substance (Fig. 11-185). For a certain distance the connective tissue of the pia mater continues to surround these penetrating vessels, as it does the larger vessels on the brain surface. Between the connective tissue of the pia mater and the penetrating vessels is found a true **perivascular space** that is directly continuous with the subarachnoid space. As the penetrating vessels branch to form the capillary networks, however, the connective tissue of the pia mater is *lost*. The basement membrane of the endothelial cells of the capillaries lies immediately adjacent to the neural tissue and is almost surrounded by the perivascular endfeet of astrocytes. Helping to complete this pia-glial perivascular sheath are a few processes from oligodendrocytes and perhaps even a few neuronal processes.

### Spinal Pia Mater

The spinal pia mater (Figs. 11-29; 11-186) is thicker, firmer, and less vascular than the cranial pia mater. Like the cranial pia, it consists of an outer layer formed by collagenous and elastic connective tissue and an inner layer formed by the basement membrane of the endothelial cells of the capillaries onto which attach the perivascular neuroglial processes (the pia-glial membrane). The spinal pia mater is intimately adherent to the surface of the spinal cord, and on the anterior spinal surface it dips into the ventral median fissure and thereby lines the two medial surfaces of that fissure. Longitudinally along the surface of the cord at the ventral median fissure, the pia mater is somewhat thickened and forms a band of connective tissue, called the **linea splendens**, that courses along the length of the fissure. Other concentrations of fibers along each side form the **denticulate ligaments** (see following).

**Fig. 11-186.** The spinal cord and its meninges. Upper portion shows the dura mater intact; intermediate portion shows the dura reflected and the arachnoid intact; lower portion shows the dura reflected and the arachnoid removed to reveal the pia mater.

From the caudal tip of the conus medullaris, the pia mater continues as a long, slender filament called the **filum terminale**. This descends within the vertebral canal and is centrally located among the spinal roots that form the cauda equina (Fig. 11-27). The filum terminale blends with the dura mater at the lower border of the second sacral vertebra, and then it extends downward as far as the base of the coccyx, where it fuses with the periosteum. Because it is thought to assist in maintaining the spinal cord in place during movements of the trunk, the filum terminale has sometimes been called the central ligament of the spinal cord.

**DENTICULATE LIGAMENTS.** The denticulate ligaments are two narrow, longitudinally oriented fibrous bands of pia mater, one situated on each of the two sides of the spinal cord. Each ligament spreads laterally toward the dura mater from the entire length of the spinal cord, midway between the dorsal-ventral sites of attachment of the posterior and anterior roots (Figs. 11-29; 11-186). Thus, the medial border of each ligament is continuous with the pia mater at the side of the spinal cord, while the scalloped lateral border presents a series of triangular, tooth-like processes, the points of which are fixed at

intervals to the dura mater. There are 21 of these pointed processes and each extends laterally through the arachnoid to become attached to the inner surface of the dura mater. The uppermost is attached to the dura opposite the margin of the foramen magnum, between the vertebral artery and the hypoglossal nerve. Each successive process

extends laterally between the spinal nerves intersegmentally, so that the most caudal is found between the sites of exit of the last thoracic and first lumbar nerves. These ligaments, along with the nerve roots, assist in suspending the spinal cord within the subarachnoid cavity.

# 12

## The Peripheral Nervous System

Nervous impulses are conveyed to and from the nervous system by the nerve trunks that form the **peripheral nervous system**. It is composed of nerve fibers, ganglia, and end organs. Afferent or sensory fibers carry toward the central nervous system the impulses arising from stimulation of sensory end organs. Efferent or motor fibers carry impulses from the central nervous system to the muscles and other responsive organs. The somatic fibers, both afferent and efferent, are associated with the general body, typified by the skeletal muscles and skin. The visceral fibers are also both afferent and efferent, and are associated with the internal organs, vessels, and mucous membranes.

The peripheral nervous system consists of (a) the cranial nerves, (b) the spinal nerves, and (c) the sympathetic nervous system. These three morphologic subdivisions are

not functionally independent, but combine and communicate with each other to supply both somatic and visceral structures with afferent and efferent fibers. For example, the efferent impulses for control of the viscera are carried partly by the sympathetic system and partly by portions of certain cranial and sacral nerves. The latter are grouped under the name parasympathetic or craniosacral system, and both sympathetic and parasympathetic systems together make up the visceral motor or autonomic nervous system, which is described in later pages.

### Cranial Nerves

The **cranial nerves** (*nervi craniales*; cerebral nerves) are attached to the base of the brain (Fig. 11-89) and make their passage from the cranial cavity through various openings or foramina in the skull (Fig. 12-1). There are 12 pairs, and beginning with the most anterior, they are designated by Roman numerals and named as follows:

- I. Olfactory
- II. Optic
- III. Oculomotor
- IV. Trochlear
- V. Trigeminal
- VI. Abducent
- VII. Facial
- VIII. Vestibulocochlear
- IX. Glossopharyngeal
- X. Vagus
- XI. Accessory
- XII. Hypoglossal

In addition to the commonly described cranial nerves, there is a small nerve named the **nervus terminalis**, which some comparative anatomists classify **morphologically** as the first cranial nerve. The nervus terminalis (*terminal nerve*) originates from the cerebral hemisphere in the region of the olfactory trigone, courses anteriorly along the medial surface of the olfactory tract and bulb to the lateral surface of the crista galli, and passes through the anterior part of the cribriform plate of the ethmoid bone. It is a compact bundle beside the olfactory tract, a close plexus beside the bulb, and a loose plexus on the crista galli, where it is embedded in the dura mater some distance above the cribriform bone. Within the cranium, fila-

**Fig. 12-1.** Interior of base of skull, showing dura mater, dural sinuses and exit of cranial nerves. (Redrawn from Töndury.)

ments join the olfactory bundles and vomeronasal nerves, and apparently pass to the mucous membrane of the septum along with them. The majority of filaments form a single strand that passes through the cribriform plate anterior to the vomeronasal nerves and is distributed to the membrane near the anterior superior border of the nasal septum. In the nasal cavity, the nerve communicates with the medial nasal branch of the anterior ethmoidal branch of the ophthalmic division of the trigeminal nerve.

In the embryo, a loose mass of fibers and cells in the portion of the nerve medial to the rostral end of the olfactory bulb is called the **ganglion terminale**. The nerve fibers are unmyelinated and ganglion cells are scattered in groups along the peripheral course of the nerve. The cells in the ganglion and along the nerve have been described by different authors as unipolar, bipolar, and multipolar (Pearson, 1941).

The central connections of the nervus terminalis end in the septal nuclei, the olfactory lobe, the posterior precommissural region, and the anterior portion of the supraoptic region of the brain. Those in the first three areas are sensory; those in the supraoptic region may be preganglionic autonomic fibers associated with the serous glands (of Bowman<sup>1</sup>) or with blood vessels in the olfactory membrane (Larsell, 1950).

### I. OLFACTORY NERVE

The **olfactory nerve** (*nervus olfactorius*; *first nerve*) (Fig. 12-2), or nerve of smell, in its properly restricted sense is represented on both sides of the nasal cavity by bundles of nerve fibers which are the central processes

<sup>1</sup>Sir William Bowman (1816-1892): An English physician (London).

**FIG. 12-2.** The nerves of the right side of the septum of the nose.

of the neuroepithelial cells in the olfactory mucous membrane of the nose. These cells are described in more detail as part of the organ of smell in Chapter 13. The nerve fibers make a plexiform network in the mucous membrane of the superior nasal concha and the part of the septum opposite, and then are gathered into approximately 20 bundles that pass through the foramina of the cribriform plate of the ethmoid bone in two groups. A lateral group comes from the concha; a medial group, from the septum. The fibers are unmyelinated, and the bundles have connective tissue sheaths derived from the tissues of the dura, arachnoid, and pia mater. After passing through the foramina, the fibers end in the glomeruli of the olfactory bulb, an oval mass approximately 3 mm  $\times$  15 mm, which rests against the intracranial surface of the cribriform plate of the ethmoid (Fig. 12-1).

Although the olfactory bulb and its connection with the brain, the olfactory tract, have a gross appearance like that of a nerve, they are more accurately classified as parts of the brain. They are components of the rhinencephalon, the portion of the brain associated with the sense of smell, which is described in Chapter 11.

The **vomeronasal nerve**, which is an important part of the olfactory system in macrosmatic animals, is present in the human fetus but disappears before birth. The nerve fibers originate in the olfactory epithelial cells of the vomeronasal organ (organ of Jacobson<sup>1</sup>), a rudiment of which may persist in man; they pass upward in the submucous tissue of the nasal septum and through the cribriform plate of the ethmoid bone to end in the accessory olfactory bulb.

## II. OPTIC NERVE

The **optic nerve** (*n. opticus*; *second nerve*) (Fig. 12-3), or nerve of sight, consists mainly of the axons or central processes of the cells in the ganglionic layer of the retina. Within the bulb of the eye, these axons lie in the stratum opticum or layer of nerve fibers of the retina (see next chapter). They converge toward the optic papilla, or disc, which is 3 mm medial to the posterior pole of the bulb, where they are gathered into small bundles that pierce the choroid and scleral

<sup>1</sup>Ludwig Levin Jacobson (1783-1843): A Danish anatomist and physician (Copenhagen).

## Outline of the Cranial Nerves

Nerves	Components	Function	Central Connection	Cell Bodies	Peripheral Distribution
I. Olfactory	Afferent Special visceral	Smell	Olfactory bulb and tract	Olfactory epithelial cells	Olfactory nerves
II. Optic	Afferent Special somatic	Vision	Optic nerve and tract	Ganglion cells of retina	Rods and cones of retina
III. Oculomotor	Efferent Somatic	Ocular movement	Nucleus III	Nucleus III	Branches to levator palpebrae; rectus superior, medius, inferior; obliquus inferior
	Efferent General visceral	Contraction of pupil and accommodation	Nucleus of Edinger-Westphal	Nucleus of Edinger-Westphal	Ciliary ganglion; ciliaris and sphincter pupillae
IV. Trochlear	Afferent Proprioceptive	Muscular sensibility	Nucleus mesencephalicus V	Nucleus mesencephalicus V	Sensory endings in ocular muscles
	Efferent Somatic	Ocular movement	Nucleus IV	Nucleus IV	Branches to obliquus superior
	Afferent Proprioceptive	Muscular sensibility	Nucleus mesencephalicus V	Nucleus mesencephalicus V	Sensory endings in obliquus superior
V. Trigeminal	Afferent General somatic	General sensibility	Trigeminal sensory nucleus	Trigeminal ganglion (Gasserian)	Sensory branches of ophthalmic, maxillary and mandibular nerves to skin and mucous membranes of face and head
	Efferent Special visceral	Mastication	Motor V nucleus	Motor V nucleus	Branches to temporalis, masseter, pterygoid, mylohyoid, digastric, tensores tympani and palatini muscles
VI. Abducent	Afferent Proprioceptive	Muscular sensibility	Nucleus mesencephalicus V	Nucleus mesencephalicus V	Sensory endings in muscles of mastication
	Efferent Somatic	Ocular movement	Nucleus VI	Nucleus VI	Branches to rectus lateralis
	Afferent Proprioceptive	Muscular sensibility	Nucleus mesencephalicus V	Nucleus mesencephalicus V	Sensory endings in rectus lateralis
VII. Facial	Efferent Special visceral	Facial expression	Motor VII nucleus	Motor VII nucleus	Branches to facial muscles, stapedius, stylohyoid, digastric muscles
	Efferent General visceral	Glandular secretion	Nucleus salivatorius	Nucleus salivatorius	Greater petrosal nerve, pterygopalatine ganglion, with branches of maxillary V to glands of nasal mucosa. Chorda tympani, lingual nerve, submandibular ganglion, submandibular and sublingual glands
	Afferent Special visceral	Taste	Nucleus tractus solitarius	Geniculate ganglion	Chorda tympani, lingual nerve, taste buds, anterior tongue
	Afferent General visceral	Visceral sensibility	Nucleus tractus solitarius	Geniculate ganglion	Great petrosal, chorda tympani and branches

VIII. Vestibulo-cochlear	Afferent	General somatic	Cutaneous sensibility	Nucleus spinal tract of V	Geniculate ganglion	With auricular branch of vagus to external ear and mastoid region
	Afferent	Special somatic	Hearing	Cochlear nuclei	Spiral ganglion	Organ of Corti in cochlea
	Afferent	Proprioceptive	Sense of equilibrium	Vestibular nuclei	Vestibular ganglion	Semicircular canals, sacculle, and utricle
	Afferent	Special visceral	Taste	Nucleus tractus solitarius	Inferior ganglion IX	Lingual branches, taste buds, posterior tongue
IX. Glossopharyngeal	Afferent	General visceral	Visceral sensibility	Nucleus tractus solitarius	Inferior ganglion IX	Tympanic nerve to middle ear, branches to pharynx and tongue, carotid sinus nerve
	Efferent	General visceral	Glandular secretion	Nucleus salivatorius	Nucleus salivatorius	Tympanic, lesser petrosal nerves, otic ganglion, with auriculotemporal V to parotid gland
	Efferent	Special visceral	Swallowing	Nucleus ambiguus	Nucleus ambiguus	Branch to stylopharyngeus muscle
	Efferent	General visceral	Involuntary muscle and gland control	Dorsal motor nucleus X	Dorsal motor nucleus X	Cardiac nerves and plexus; ganglia on heart. Pulmonary plexus; ganglia, respiratory tract. Esophageal, gastric, celiac plexuses; myenteric and submucous plexuses, muscles and glands of digestive tract down to transverse colon
X. Vagus	Efferent	Special visceral	Swallowing and phonation	Nucleus ambiguus	Nucleus ambiguus	Pharyngeal branches, superior and inferior laryngeal nerves
	Afferent	General visceral	Visceral sensibility	Nucleus tractus solitarius	Inferior ganglion X	Fibers in all cervical, thoracic, and abdominal branches; carotid and aortic bodies
	Afferent	Special visceral	Taste	Nucleus tractus solitarius	Inferior ganglion X	Branches to region of epiglottis and taste buds
	Afferent	General somatic	Cutaneous sensibility	Nucleus spinal tract V	Superior ganglion X	Auricular branch to external ear and meatus
XI. Accessory	Efferent	Special visceral	Swallowing and phonation	Nucleus ambiguus	Nucleus ambiguus	Bulbar portion, communication with vagus, in vagus branches to muscles of pharynx and larynx
	Efferent	Special somatic	Movements of shoulder and head	Lateral column of upper cervical spinal cord	Lateral column of upper cervical spinal cord	Spinal portion, branches to sternocleidomastoid and trapezius muscles
XII. Hypoglossal	Efferent	General somatic	Movements of tongue	Nucleus XII	Nucleus XII	Branches to extrinsic and intrinsic muscles of tongue

**Fig. 12-3.** The left optic nerve and the optic tracts.

coats through the many small foramina of the lamina cribrosa sclerae to form the optic nerve. The optic nerve, as it courses posteriorly toward the brain, traverses the central region of the orbit, passes through the optic canal (foramen), and then, approaching the nerve of the other side, joins it to form the optic chiasma. From the chiasma, the fibers continue in the optic tracts, which diverge from each other and reach the base of the brain near the cerebral peduncle. The central connections of the fibers are described in Chapter 11.

### **Parts of the Optic Nerve**

The optic nerve has four portions, contained in: (a) the bulb, (b) the orbit, (c) the optic canal, and (d) the cranial cavity.

**INTRAOCULAR PORTION.** The intraocular portion is very short, about 1 mm, and the nerve fibers within it are unmyelinated until they pass through the lamina cribrosa, at which point they become myelinated and supported by neuroglia.

**ORBITAL PORTION.** The orbital portion, 3 to 4 mm in diameter, is 20 to 30 mm long; its course is slightly sinuous, which allows greater length for unrestricted movement of the eyeball. It is invested by sheaths derived from the dura, arachnoid, and pia mater, all three of which fuse and become continuous with the sclera at the lamina cribrosa; the dura extends as far back as the cranial cavity, the arachnoid somewhat farther, and the pia all the way to the chiasma. The pia

closely ensheathes the nerve and sends numerous septa into its substance, carrying the blood supply. Between the sheaths are subarachnoid and subdural spaces similar to and continuous with those of the cranial cavity, the subarachnoid ends in a cul-de-sac at the lamina cribrosa. As it traverses the orbit, the optic nerve is surrounded by the posterior part of the fascia bulbi (Tenon's capsule<sup>1</sup>), the orbital fat, and, in its anterior two-thirds, by the ciliary nerves and arteries. Toward the posterior part of the orbit, it is crossed obliquely by the nasociliary nerve, the ophthalmic artery, the superior ophthalmic vein, and the superior division of the oculomotor nerve. Farther toward the roof of the orbit are the rectus superior and levator palpebrae superioris muscles, and the trochlear and frontal nerves. Inferior to it are the inferior division of the oculomotor nerve and the rectus inferior muscle; medial to it is the rectus medialis muscle; and lateral to it are the abducent nerve and rectus lateralis muscle. In the posterior part of the orbit are the ciliary ganglion and the ophthalmic artery (Fig. 12-6). As it passes into the optic canal, accompanied by the ophthalmic artery, it is surrounded by the common anular tendon (of Zinn<sup>2</sup>), which serves as the origin of the ocular muscles. A short distance behind the bulb, the optic nerve is pierced by the central artery of the retina and its accompanying vein. These vessels enter the bulb through an opening in the lamina cribrosa and supply the retina.

**OPTIC CANAL PORTION.** Within the optic canal, the ophthalmic artery lies inferior to the nerve, just after it has branched from the internal carotid artery. Medially, separated by a thin plate of bone, is the sphenoidal air sinus. If the pneumatization of the bone is extensive, the nerve may be almost completely surrounded by the sphenoidal sinus or the posterior ethmoidal cells. Superior to the nerve, the three sheaths—dura, arachnoid, and pia—are fused to each other, to the nerve, and to the periosteum of the bone, thereby fixing the nerve and preventing it from being forced back and forth in the foramen. The subarachnoid and subdural spaces are present only below the nerve.

<sup>1</sup>Jacques René Tenon (1724–1816): A French pathologist and surgeon (Paris).

<sup>2</sup>Johann Gottfried Zinn (1727–1759): A German professor of medicine and botanist (Göttingen).

**INTRACRANIAL PORTION.** The intracranial portion of the nerve (Fig. 12-1) rests on the anterior part of the cavernous sinus and on the diaphragma sellae, which overlies the hypophysis. The part of the brain above the nerve is the anterior perforated substance. The internal carotid artery approaches the nerve laterally and then is directly inferior to it at the origin of the ophthalmic artery. The anterior cerebral artery crosses superior to it.

### *Optic Chiasma*

The **optic chiasma** (Fig. 12-3), as the name indicates, resembles the Greek letter "X" from the convergence of the optic nerves in front and the divergence of the optic tracts behind. It rests upon the tuberculum sellae of the sphenoid bone and on the diaphragma sellae of the dura. It is continuous superiorly with the lamina terminalis, and posteriorly, with the tuber cinereum and the infundibulum of the hypophysis. Lateral to the optic chiasma, on each side, are the anterior perforated substance and the internal carotid artery.

### *Optic Tract*

The **optic tract** leaves the chiasma and diverges from its fellow of the opposite side until it reaches the cerebral peduncle, where it winds obliquely across the undersurface. It is adjacent to the tuber cinereum and peduncle, thus having contact with the third ventricle. As it terminates, a shallow groove divides it into a medial and lateral root. The lateral root contains fibers of visual function and ends in the lateral geniculate body. The medial root carries fibers that decussate (commissure of Gudden<sup>1</sup> and probably other nonvisual commissures, those of Meynert<sup>2</sup> and Darkschewitsch<sup>3</sup>).

The fibers lying medially in the optic nerve cross in the chiasma and continue in the optic tract of the other side. The lateral fibers are uncrossed and continue to the brain in the optic tract of the same side. The

fibers from the two sides become intermingled in the tract.

The optic nerve corresponds to a tract of fibers within the brain rather than to the other cranial nerves because of its embryologic development and its structure. It develops from a diverticulum of the lateral aspect of the forebrain; its fibers probably are third in the chain of neurons from the receptors to the brain. The fibers are supported by neuroglia instead of neurilemmal sheaths, and the nerve has three sheaths prolonged from the corresponding meninges of the brain (see Chapter 13).

## III. OCULOMOTOR NERVE

The **oculomotor nerve** (Figs. 12-6; 12-7) supplies the levator palpebrae superioris muscle, the extrinsic muscles of the eye except the obliquus superior and rectus lateralis, and the intrinsic muscles with the exception of the dilator pupillae. Its superficial origin is from the midbrain at the oculomotor sulcus on the medial side of the cerebral peduncle. Its deep origin and central connections within the brain are described in Chapter 11. The oculomotor nerve is traditionally considered a motor nerve, containing special somatic efferent fibers for the ocular muscles and parasympathetic fibers for the ciliary ganglion, but experimental evidence indicates that it contains proprioceptive fibers from cells in the brain stem near the motor cells (Corbin and Oliver, 1942).

As it emerges from the brain into the posterior cranial fossa, the nerve is invested with pia mater, and is bathed in the cerebrospinal fluid of the cisterna interpeduncularis (basalis). It passes between the superior cerebellar and posterior cerebral arteries near the termination of the basilar artery. It is covered with arachnoid lateral to the posterior clinoid process, and between the anterior and posterior clinoid processes it pierces the dura (Fig. 12-1) by passing between the free and attached borders of the tentorium cerebelli. It runs anteriorly, embedded in the lateral wall of the cavernous sinus (Fig. 12-13), superior to the other orbital nerves. It enters the superior orbital fissure between the two heads of the rectus lateralis (Fig. 12-4) in two divisions, a superior and an inferior. Within the fissure, the trochlear, lacrimal, and fron-

<sup>2</sup>Theodor Herman Meynert (1833-1892): An Austrian professor of neurology and psychiatry (Vienna).

<sup>3</sup>Liverij Osipovich Darkschewitsch (1858-1925): A Russian neurologist (St. Petersburg).

**FIG. 12-4.** Dissection showing origins of right ocular muscles, and nerves entering through the superior orbital fissure.

tal nerves lie superior to it, the abducent nerve lies inferior and lateral to it, and the nasociliary nerve passes between its two divisions.

Two **communications** join the oculomotor nerve as it runs along the wall of the cavernous sinus: (1) one from the **cavernous plexus** of the sympathetic system, carrying postganglionic fibers from the superior cervical ganglion; and (2) one from the **ophthalmic division** of the trigeminal nerve.

The **superior division** (Fig. 12-6), smaller than the inferior, passes medialward across the optic nerve and sends branches to the **rectus superior** and the **levator palpebrae superioris muscles**. The branch to the levator contains sympathetic postganglionic fibers from the cavernous plexus, which continue anteriorly to reach the nonstriated muscle attached to the superior tarsus.

The **inferior division** has four branches: to the **rectus medialis**, passing inferior to the optic nerve; to the **rectus inferior**; and to the **obliquus inferior**. The latter runs forward between the inferior and lateral recti muscles and gives off a short, rather thick branch, the **root of the ciliary ganglion**.

**CILIARY GANGLION.** The ciliary ganglion (ophthalmic or lenticular ganglion) (Figs. 12-5; 12-6) is a small parasympathetic gan-

glion (1 or 2 mm in diameter) whose preganglionic fibers come from the oculomotor nerve and whose postganglionic fibers carry motor impulses to the ciliaris and sphincter pupillae muscles. It is situated about 1 cm from the posterior boundary of the orbit, close to the lateral surface of the optic nerve and between it and the rectus lateralis muscle and the ophthalmic artery.

The **parasympathetic motor root** (*radix oculomotorii*; short root) of the ganglion is a rather short, thick nerve, which may be double. It comes from the branch of the inferior division of the oculomotor nerve that supplies the obliquus inferior and is connected with the posterior inferior angle of the ganglion. It contains preganglionic parasympathetic fibers from the Edinger-Westphal group of cells of the third nerve nucleus, which form synapses in the ganglion with cells whose postganglionic fibers pass through the short ciliary nerves into the bulb.

Two communications were formerly called roots of the ganglion: (1) a communication with the **nasociliary nerve** (long root; sensory root) joins the posterior superior angle of the ganglion; it contains sensory fibers that traverse the short ciliary nerves on their way from the cornea, iris, and ciliary body.

**FIG. 12-5.** Autonomic connections of the ciliary and superior cervical ganglia. Parasympathetic blue; sympathetic red.

**FIG. 12-6.** Nerves of the orbit, side view.

without forming synapses in the ganglion; (2) a communication with the **sympathetic** system (sympathetic root) that is a slender filament from the cavernous plexus which frequently blends with the communication with the nasociliary nerve. It contains post-ganglionic fibers from the superior cervical ganglion that pass through the ciliary ganglion without forming synapses and reach the dilator pupillae muscle and the blood vessels of the bulb through the short ciliary nerves.

The branches of the ganglion are the **short ciliary nerves**, which are six to ten delicate filaments that leave the anterior part of the ganglion in two bundles, superior and inferior. They run anteriorly with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and they are accompanied by the long ciliary nerves from the nasociliary. They pierce the sclera at the posterior part of the bulb, pass anteriorly in delicate grooves on the inner surface of the sclera, and are distributed to the ciliary body, iris, and cornea. The parasympathetic post-ganglionic fibers supply the ciliaris and sphincter pupillae muscles. The short ciliary nerves also carry sympathetic postganglionic fibers to the dilator pupillae muscle, and sensory fibers from the cornea, iris, and ciliary body.

#### IV. TROCHLEAR NERVE

The **trochlear nerve** (Fig. 12-7) is the smallest of the cranial nerves and supplies the obliquus superior oculi muscle. Its superficial origin is from the surface of the anterior medullary velum at the side of the frenulum veli, immediately posterior to the inferior colliculus. Its deep origin and central connections are described in Chapter 11.

The nerve is directed laterally across the superior cerebellar peduncle, and it winds around the cerebral peduncle near the pons. It runs anteriorly along the free border of the tentorium cerebelli for 1 or 2 cm (Fig. 12-1), pierces the dura just posterior to the posterior clinoid process, and without changing the direction of its course, takes its place in the lateral wall of the cavernous sinus (Fig. 12-13) between the oculomotor nerve and the ophthalmic division of the trigeminal nerve, to which it becomes firmly attached

Fig. 12-7. Nerves of the orbit, seen from above.

by connective tissue. It crosses the oculomotor nerve in a slightly upward course, enters the orbit through the superior orbital fissure, and becomes superior to the other nerves. In the orbit it passes medialward, above the origin of the levator palpebrae superioris (Fig. 12-4), and finally enters the orbital surface of the obliquus superior.

In the lateral wall of the cavernous sinus the trochlear nerve forms communications with the cavernous plexus of the sympathetic and with the ophthalmic division of the trigeminal nerve.

**VARIATIONS.** Occasionally sensory branches appear to come from the trochlear nerve, but they are probably aberrant fibers that have come from the ophthalmic nerve.

#### V. TRIGEMINAL NERVE

The **trigeminal nerve** is the largest of the cranial nerves. It is the great cutaneous sensory nerve of the face, the sensory nerve to the mucous membranes and other internal structures of the head, and the motor nerve of the muscles of mastication.

## Roots

The trigeminal nerve traditionally has two roots, a larger sensory root and a smaller motor root (Fig. 12-6). Investigations have also revealed a third or intermediate root.

The **sensory root** is composed of a large number of fine bundles in close association with each other that enter the pons through the lateral part of its ventral surface. The nerve fibers in the sensory root are the central processes of the ganglion cells in the trigeminal (semilunar) ganglion.

The **motor root** emerges in several bundles from the surface of the pons approximately 2 to 5 mm medial and anterior (rostral) to the sensory root. In addition to the motor fibers, the motor root includes proprioceptive sensory fibers from the mesencephalic central nucleus of the nerve (Corbin and Harrison, 1940).

The **intermediate root**, composed of one or more bundles, has an origin from the surface of the pons quite distinct from that of the other two roots (Jannetta and Rand, 1966). The bundles arise between the motor and sensory roots and are separated from them by 1 to 5 mm (Vidic and Stephanos, 1969). The internal fiber connections, function, and surgical importance of this root are not yet explained.

The three roots pass anteriorly in the posterior cranial fossa, under the shadow of the tentorium where the latter is attached to the petrous portion of the temporal bone, to the trigeminal ganglion. The deep origin and central connections of these roots are described in Chapter 11.

## Trigeminal Ganglion

The **trigeminal ganglion** (ganglion semilunare; Gasserian ganglion<sup>1</sup>) (Fig. 12-8) lies in a pocket of dura mater (cavum Meckelii<sup>2</sup>) that occupies the trigeminal impression near the apex of the petrous portion of the temporal bone (Burr and Robinson, 1925). The ganglionic mass is flat and has a semilunar shape; it is approximately 1 cm × 2 cm (Fig. 12-8). The central processes of the cells leave

the concavity and the peripheral fibers leave the convexity of the crescent.

The ganglion is lateral to the posterior part of the cavernous sinus and the internal carotid artery at the foramen lacerum, and the central fibers pass inferior to the superior petrosal sinus. The motor root, being medial to the sensory, passes beneath the ganglion (that is, between it and the petrous bone), and leaves the skull through the foramen ovale with the mandibular nerve. The greater petrosal nerve also passes between the ganglion and the bone. The ganglion receives filaments from the carotid plexus of the sympathetic system, and it gives off minute branches to the tentorium cerebelli and to the dura mater of the middle cranial fossa.

The peripheral fibers from the ganglion are collected into three large divisions: (1) the ophthalmic, (2) the maxillary, and (3) the mandibular nerves. The ophthalmic and maxillary nerves remain sensory, but the mandibular nerve becomes mixed, being joined by the motor root just outside the skull.

Four small ganglia are associated with these nerves: the ciliary ganglion with the ophthalmic, the pterygopalatine with the maxillary, and the otic and submandibular with the mandibular. These ganglia are not a part of the trigeminal complex functionally, however, and the trigeminal fibers that communicate with them pass through without synapses. The ganglia are parasympathetic and are therefore described with the nerves that supply their motor roots with preganglionic fibers (viz., the ciliary ganglion with the oculomotor nerve, the pterygopalatine and submandibular ganglia with the facial nerve, and the otic ganglion with the glossopharyngeal nerve.

## Ophthalmic Nerve

The **ophthalmic nerve** (Figs. 12-6; 12-7), or first division of the trigeminal, leaves the anterior superior part of the trigeminal ganglion and enters the orbit through the superior orbital fissure. It is a flat band about 2.5 cm long and lies in the lateral wall of the cavernous sinus, inferior to the oculomotor and trochlear nerves (Fig. 12-13). It is a sensory nerve, supplying the bulb of the eye, conjunctiva, lacrimal gland, part of the mucous membrane of the nose and paranasal

<sup>1</sup>Johann Laurenz Gasser (?-1765): An Austrian anatomist (Vienna).

<sup>2</sup>Johann Friedrich Meckel (the Elder, 1714-1774): A German anatomist and obstetrician (Berlin).

sinuses, and the skin of the forehead, eyelids, and nose.

The ophthalmic nerve is joined by communicating sympathetic filaments from the **cavernous plexus** and communicates with the **oculomotor, trochlear, and abducent nerves**. It gives off a recurrent filament to the dura mater, and just before it passes through the superior orbital fissure it divides into three other branches: frontal, lacrimal, and nasociliary.

#### BRANCHES AND COMMUNICATIONS OF OPHTHALMIC NERVE

##### Tentorial Branch

The tentorial branch (Fig. 12-7, recurrent filament) arises near the ganglion, passes across and adheres to the trochlear nerve, and runs between the layers of the tentorium, to which it is distributed.

##### Lacrimal Nerve

The **lacrimal nerve** (Fig. 12-7) is the smallest of the three branches of the ophthalmic nerve. It passes anteriorly in a separate tube of dura mater, and enters the orbit through the narrowest part of the superior orbital fissure. In the orbit it runs along the superior border of the rectus lateralis muscle close to the periorbital, and enters the lacrimal gland with the lacrimal artery, giving off filaments to supply the gland and adjacent conjunctiva. Finally, it pierces the orbital septum and ends in the skin of the upper eyelid, joining with filaments of the facial nerve.

In the orbit, through a communication with the **zygomatic branch of the maxillary nerve** (Figs. 12-6; 12-8), it receives postganglionic parasympathetic fibers, which are the secretomotor fibers for the lacrimal gland. These fibers pass from their cells of origin in the pterygopalatine ganglion through the pterygopalatine nerves to the maxillary nerve, then along the zygomatic and zygomaticotemporal nerves, finally traversing the communication just mentioned and being distributed with the branches of the lacrimal nerve to the gland. The preganglionic fibers reach the ganglion from the facial nerve by way of the greater petrosal nerve.

**VARIATIONS.** The lacrimal nerve is occasionally absent, and its place is then taken by the zygomaticotemporal branch of the maxillary nerve. Sometimes the latter is absent and a communication of the lacrimal is substituted for it.

##### Frontal Nerve

The **frontal nerve** (Fig. 12-7) is the largest branch of the ophthalmic nerve, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit through the superior orbital fissure, continues rostrally between the levator palpebrae superioris and the periorbital, and at a variable distance approximately halfway to the supraorbital margin, it divides into a large supraorbital and a small supratrochlear branch.

**SUPRATROCHLEAR NERVE.** The supratrochlear nerve (Fig. 12-7) bends medially to pass superior to the pulley of the obliquus superior muscle and gives off a filament that communicates with the infratrochlear branch of the nasociliary nerve. It pierces the orbital fascia, sends filaments to the conjunctiva and skin of the medial part of the upper lid, passes deep to the corrugator and frontalis muscles, and divides into branches that pierce the muscles to supply the skin of the lower and mesial part of the forehead (Fig. 12-10).

**SUPRAORBITAL NERVE.** The supraorbital nerve (Fig. 12-7), the continuation of the frontal nerve, leaves the orbit through the supraorbital notch or foramen. It gives filaments to the upper lid and continues upon the forehead, dividing into medial and lateral branches beneath the frontalis muscle (Fig. 12-10). The **medial branch**, sometimes called the **frontal branch**, is smaller; it pierces the muscle and supplies the scalp as far as the parietal bone. The larger **lateral branch** pierces the galea aponeurotica and supplies the scalp nearly as far back as the lambdoidal suture (Fig. 12-18). The supraorbital nerve may divide before leaving the orbit, in which case the lateral branch occupies the supraorbital notch or foramen and the medial or frontal branch may have a notch of its own.

**FRONTAL SINUS BRANCH.** In the supraorbital notch, a small filament pierces the bone to supply the mucous membrane of the frontal sinus.

### Nasociliary Nerve

The **nasociliary nerve** (Fig. 12-7) is intermediate in size between the frontal and lacrimal nerves and is more deeply placed in the orbit. It enters the orbit between the two heads of the rectus lateralis muscle, and between the superior and inferior divisions of the oculomotor nerve. It passes across the optic nerve and runs obliquely inferior to the rectus superior and obliquus superior muscles to the medial wall of the orbital cavity. Here it passes through the anterior ethmoidal foramen as the **anterior ethmoidal nerve** and enters the cranial cavity just superior to the cribriform plate of the ethmoid bone. It runs along a shallow groove on the lateral margin of the plate, and penetrating the bone through a slit at the side of the crista galli, it enters the nasal cavity. It supplies branches to the mucous membrane of the nasal cavity (Figs. 12-2; 12-12). Finally, it emerges between the inferior border of the nasal bone and the lateral nasal cartilage as the external nasal branch.

**BRANCHES OF THE NASOCILIARY NERVE.** The **communication with the ciliary ganglion** (long or sensory root of the ganglion) (Fig. 12-6) usually arises from the nasociliary nerve between the two heads of the rectus lateralis muscle. It runs anteriorly on the lateral side of the optic nerve and enters the posterior superior angle of the ciliary ganglion. It contains sensory fibers that pass through the ganglion without synapses and continue on into the bulb by way of the short ciliary nerves. It is sometimes joined by a filament from the cavernous plexus of sympathetic fibers or from the superior ramus of the oculomotor nerve. The ciliary ganglion is described with the oculomotor nerve.

Two or three **long ciliary nerves** are given off from the nasociliary nerve as it crosses the optic nerve. They accompany the short ciliary nerves from the ciliary ganglion, pierce the posterior part of the sclera, and running anteriorly between it and the choroid, are distributed to the iris and cornea. In addition to afferent fibers, the long ciliary nerves probably contain sympathetic fibers from the superior cervical ganglion to the dilator pupillae muscle, which passes through the communication between the cavernous plexus and the ophthalmic nerve.

The **infratrochlear nerve** (Fig. 12-7) is given off from the nasociliary nerve just before it enters the anterior ethmoidal foramen. It runs anteriorly along the superior border of the rectus medialis muscle and is joined near the pulley of the obliquus superior by a filament from the supratrochlear nerve. It then passes to the medial angle of the eye and supplies the skin of the eyelids and side of the nose, the conjunctiva, the lacrimal sac, and the caruncula lacrimalis (Fig. 12-10).

The **ethmoidal branches** supply the mucous membrane of the sinuses. The **posterior ethmoidal nerve** leaves the orbit through the posterior ethmoidal foramen and supplies the posterior ethmoidal and the sphenoidal sinuses. The **anterior ethmoidal branches** are filaments that are given off as the nerve passes through the anterior ethmoidal foramen; they supply the anterior ethmoidal and frontal sinuses.

The **internal nasal branches** supply the mucous membrane of the anterior part of the septum and lateral wall of the nasal cavity (Figs. 12-2; 12-12).

The **external nasal branch** emerges between the nasal bone and the lateral nasal cartilage, passes deep to the nasalis muscle, and supplies the skin of the ala and the apex of the nose (Fig. 12-8).

### Maxillary Nerve

The **maxillary nerve** (superior maxillary nerve) (Fig. 12-8), or second division of the trigeminal, arises from the middle of the trigeminal ganglion. It is intermediate between the other two divisions in size and position, and like the ophthalmic nerve, it is entirely sensory. It supplies the skin of the middle portion of the face, lower eyelid, side of the nose, and the upper lip (Fig. 12-10); the mucous membrane of the nasopharynx, maxillary sinus, soft palate, tonsil and roof of the mouth; and the upper gums and teeth. It passes horizontally rostralward, at first in the inferior part of the lateral wall of the cavernous sinus and then beneath the dura to the foramen rotundum, through which it leaves the cranial cavity. From the foramen rotundum, it crosses the pterygopalatine fossa, inclines lateralward in a groove on the posterior surface of the maxilla, and enters the orbit through the inferior orbital fissure.

FIG. 12-8. Distribution of the maxillary and mandibular nerves, and the submandibular ganglion.

In the posterior part of the orbit it becomes the **infraorbital nerve**, lies in the infraorbital groove, and, continuing rostralward, dips into the infraorbital canal. It emerges into the face through the infraorbital foramen, where it is deep to the levator labii superioris, and divides into branches for the skin of the face, nose, lower eyelid, and upper lip.

The branches of the maxillary nerve may be divided into four groups, those given off: (1) in the cranium, (2) in the pterygopalatine fossa, (3) in the infraorbital canal, and (4) in the face.

#### BRANCHES IN THE CRANIUM

The **middle meningeal nerve** (meningeal or dural branch) is given off from the maxillary nerve directly after its origin from the trigeminal (semilunar) ganglion; it accompanies the middle meningeal artery and supplies the dura mater.

#### BRANCHES IN THE PTERYGOPALATINE FOSSA

##### Zygomatic Nerve

The **zygomatic nerve** (temporomalar nerve; orbital nerve) (Fig. 12-6) arises in the pterygopalatine fossa, enters the orbit by the inferior orbital fissure, and divides into two branches, zygomaticotemporal and zygomaticofacial.

**ZYGOMATICOTEMPORAL BRANCH.** The zygomaticotemporal branch runs along the lateral wall of the orbit in a groove in the zygomatic bone, and passing through a small foramen or through the sphenozygomatic suture, enters the temporal fossa. It runs upward between the bone and substance of the temporalis muscle, pierces the temporal fascia about 2.5 cm above the zygomatic arch, is distributed to the skin of the side of the forehead, and communicates with the facial nerve and with the auriculotemporal branch of the mandibular nerve. As it

pierces the temporal fascia, it gives off a slender twig, which runs between the two layers of the fascia to the lateral side of the orbit (Fig. 12-18).

Before it leaves the orbit, it sends a communication to the **lacrimal nerve** through which the postganglionic parasympathetic fibers from the pterygopalatine ganglion reach the lacrimal gland (Fig. 12-8).

**ZYGOMATICOFACIAL BRANCH.** The zygomaticofacial branch (*malar branch*) passes along the inferior lateral angle of the orbit, through the zygomatic bone by way of the zygomaticoörbital and zygomaticofacial foramina, emerges upon the face, and perforating the orbicularis oculi muscle, supplies the skin on the prominence of the cheek. It joins with the facial nerve and with the inferior palpebral branches of the infraorbital nerve (Fig. 12-18).

**VARIATIONS.** The two branches vary in size, a deficiency in one being made up by the other or by the lacrimal or infraorbital nerves.

### Pterygopalatine Nerves

The **pterygopalatine nerves** (sphenopalatine nerves) (Figs. 12-8; 12-9) are two short trunks that unite at the pterygopalatine ganglion and then are redistributed into branches. Formerly these trunks were called the sensory

roots of the ganglion, and their peripheral branches were listed as the branches of distribution of the ganglion. Since most fibers in the trunks are trigeminal somatic afferents that merely pass beside or through the ganglion without synapses, the branches are listed here as belonging to the maxillary nerve rather than the ganglion. The ganglion is described with the facial nerve.

The pterygopalatine nerves serve also as important functional communications between the ganglion and the maxillary nerve. Postganglionic parasympathetic secretomotor fibers from the ganglion pass through them and back along the main maxillary nerve to the zygomatic nerve, through which they are routed to the lacrimal nerve and lacrimal gland. Other fibers from the ganglion accompany the branches of distribution of the maxillary nerve to the glands of the nasal cavity and palate.

The **branches of distribution** from the pterygopalatine nerves are divisible into four groups: (1) orbital, (2) palatine, (3) posterior superior nasal, and (4) pharyngeal.

**ORBITAL BRANCHES.** The orbital branches (*ascending branches*) are two or three delicate filaments that enter the orbit by the inferior orbital fissure and supply the periosteum. Filaments pass through foramina in the frontoethmoidal suture to supply the mucous membrane of the posterior ethmoidal and sphenoidal sinuses.

**FIG. 12-9.** The pterygopalatine ganglion and nasal and palatine nerves.

**GREATER PALATINE NERVE.** The greater palatine nerve (anterior palatine nerve; descending branch) (Figs. 12-9; 12-12) passes through the pterygopalatine canal, emerges upon the hard palate through the greater palatine foramen, and divides into several branches, the longest of which passes anteriorly in a groove in the hard palate nearly as far as the incisor teeth. It supplies the gums and mucous membrane of the hard palate and adjacent parts of the soft palate, and communicates with the terminal filaments of the nasopalatine nerve.

**Posterior Inferior Nasal Branches.** These branches leave the nerve while it is in the canal, enter the nasal cavity through openings in the palatine bone, and ramify over the inferior nasal concha and middle and inferior meatuses.

**Lesser Palatine Nerves.** These nerves (Fig. 12-9) emerge through the lesser palatine foramina and distribute branches to the soft palate, uvula, and tonsil. They join with the tonsillar branches of the glossopharyngeal nerve to form a plexus around the tonsil (*circulus tonsillaris*). Many of the somatic afferent fibers contained in the lesser palatine nerves belong to the facial nerve, have their cells in the geniculate ganglion, and traverse

the greater petrosal nerve and the nerve of the pterygoid canal (Vidian<sup>1</sup> nerve).

**POSTERIOR SUPERIOR NASAL BRANCHES.** The posterior superior nasal branches enter the posterior part of the nasal cavity by the sphenopalatine foramen and supply the mucous membrane covering the superior and middle conchae, the lining of the posterior ethmoid sinuses, and the posterior part of the septum. One branch, longer and larger than the others, and named the **nasopalatine nerve**, passes across the roof of the nasal cavity inferior to the ostium of the sphenoidal sinus to reach the septum. It runs obliquely forward and downward, lying between the mucous membrane and periosteum of the septum, to the incisive canal (Fig. 12-2). It passes through the canal and communicates with the corresponding nerve of the opposite side and with the greater palatine nerve.

**PHARYNGEAL BRANCH.** The pharyngeal branch (pterygopalatine nerve) (Fig. 12-9) leaves the posterior part of the pterygopalatine ganglion. It passes through the pharynx-

<sup>1</sup>Vidus Vidius (Guido Guidi, 1500-1569): An Italian physician and professor of medicine (Pisa).

**Fig. 12-10.** Sensory areas of the head, showing the general distribution of the three divisions of the fifth nerve. (Modified from Testut.)

geal canal with the pharyngeal branch of the maxillary artery, and is distributed to the mucous membrane of the nasal part of the pharynx posterior to the auditory tube.

### Posterior Superior Alveolar Branches

The **posterior superior alveolar branches** (*posterior superior dental branches*) (Fig. 12-8) arise from the trunk of the nerve just before it enters the infraorbital groove; there are generally two, but sometimes they arise by a single trunk. They cross the tuberosity of the maxilla and give off several twigs to the gums and neighboring parts of the mucous membrane of the cheek. They then enter the posterior alveolar canals on the infratemporal surface of the maxilla, and passing anteriorly in the substance of the bone, communicate with the middle superior alveolar nerve. They give off branches to the lining membrane of the maxillary sinus and three twigs to each molar tooth; these twigs enter the foramina at the apices of the roots of the teeth.

### BRANCHES IN INFRAORBITAL CANAL

**MIDDLE SUPERIOR ALVEOLAR BRANCH.** The middle superior alveolar branch (*middle superior dental branch*) is given off from the nerve in the posterior part of the infraorbital canal, and runs downward and forward in a canal in the lateral wall of the maxillary sinus to supply the two premolar teeth. It forms a superior dental plexus with the anterior and posterior superior alveolar branches.

**ANTERIOR SUPERIOR ALVEOLAR BRANCH.** The large anterior superior alveolar branch (*anterior superior dental branch*) (Fig. 12-8) is given off from the nerve just before its exit from the infraorbital foramen; it courses in a canal in the anterior wall of the maxillary sinus, and divides into branches that supply the incisor and canine teeth. It communicates with the middle superior alveolar branch and gives off a nasal branch, which passes through a minute canal in the lateral wall of the inferior meatus and supplies the mucous membrane of the anterior part of the inferior meatus and the floor of the nasal cavity, communicating with the nasal branches from the pterygopalatine nerves.

The **infraorbital nerve** emerges through the infraorbital foramen and supplies the branches to the face (Fig. 12-10).

### BRANCHES IN THE FACE

**INFERIOR PALPEBRAL BRANCHES.** The inferior palpebral branches (Fig. 12-8) pass superiorly, deep to the orbicularis oculi muscle. They supply the skin and conjunctiva of the lower eyelid, joining at the lateral angle of the orbit with the facial and zygomaticofacial nerves.

**EXTERNAL NASAL BRANCHES.** The external nasal branches (Fig. 12-8) supply the skin of the side of the nose and of the septum mobile nasi. They join with the terminal twigs of the nasociliary nerve.

**SUPERIOR LABIAL BRANCHES.** The superior labial branches (Fig. 12-8), the largest and most numerous, pass deep to the levator labii superioris muscle and are distributed to the skin of the upper lip, to the mucous membrane of the mouth, and to the labial glands. They communicate immediately inferior to the orbit with filaments from the facial nerve, forming with them the **infraorbital plexus**.

### Mandibular Nerve

The **mandibular nerve** (*inferior maxillary nerve*) (Figs. 12-8; 12-11; 12-12), or third and largest division of the trigeminal, is a mixed nerve and has two roots: a *large sensory root* arising from the inferior angle of the trigeminal ganglion, and a *small motor root* (the entire motor root of the trigeminal nerve). The sensory fibers supply the skin of the temporal region, auricle, external meatus, cheek, lower lip, and lower part of the face; the mucous membrane of the cheek, tongue, and mastoid air cells; the lower teeth and gums; the mandible and temporomandibular joint; and part of the dura mater and skull. The motor fibers supply the muscles of mastication (masseter, temporalis, pterygoid), the mylohyoid and anterior belly of the digastric, and the tensores tympani and veli palatini. The two roots leave the middle cranial fossa through the foramen ovale, the motor part medial to the sensory, and unite just outside the skull. The main trunk thus formed is short, 2 or 3 mm, and divides into a smaller anterior and a larger posterior division. The otic ganglion lies close against the medial surface of the nerve, just outside the foramen ovale where the two roots fuse, and it surrounds the origin of the medial pterygoid nerve (Fig. 12-20).

A communication to the **otic ganglion**

Fig. 12-11. Mandibular division of the trigeminal nerve.

from the internal pterygoid nerve was formerly called a root of the ganglion, but the fibers pass through without synapses.

**VARIATIONS.** The two divisions are separated by a fibrous band, the pterygospinous ligament, which may become ossified, and the anterior division then passes through a separate opening in the bone, the pterygospinous foramen (foramen of Civinini<sup>1</sup>).

The branches of the main trunk of the nerve are the meningeal branch, the medial pterygoid nerve, the anterior trunk, and the posterior trunk.

#### MENINGEAL BRANCH

The meningeal branch (*nervus spinosus*, *recurrent branch*) enters the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches,

which accompany the anterior and posterior divisions of the artery and supply the dura mater. The anterior branch communicates with the meningeal branch of the maxillary nerve; the posterior sends filaments to the mucous membrane of the mastoid air cells.

#### MEDIAL PTERYGOID NERVE

The **medial pterygoid nerve** (Fig. 12-20) is a slender branch that penetrates the otic ganglion and, after a short course, enters the deep surface of the muscle. It has two small branches that have a close association with the otic ganglion and have been described as branches of the ganglion, but their fibers pass through the ganglion without interruption. These are the **nerve to the tensor veli palatini** (Fig. 12-9), which enters the muscle near its origin, and the **nerve to the tensor tympani**, which lies close to and nearly parallel with the lesser superficial petrosal nerve and penetrates the cartilage of the auditory tube to supply the muscle.

<sup>1</sup>Filippo Civinini (1805-1844): An Italian anatomist (Pisa).

**ANTERIOR TRUNK**

The anterior division of the mandibular nerve (Fig. 12-8) receives a small contribution of sensory fibers and all of the motor fibers from the motor root except those in the medial pterygoid and mylohyoid nerves. The following branches supply the muscles of mastication and the skin and mucous membrane of the cheek.

**MASSETERIC NERVE.** The masseteric nerve (Fig. 12-11) passes lateralward, above the lateral pterygoid, to the mandibular notch, which it crosses with the masseteric artery to enter the masseter muscle near its origin from the zygomatic arch. It gives a filament to the temporomandibular joint.

**DEEP TEMPORAL NERVES.** The deep temporal nerves (Fig. 12-11) are usually two, anterior and posterior, but a third or intermediate may be present. The anterior deep temporal frequently is given off from the buccal nerve; it emerges with the latter between the two heads of the lateral pterygoid muscle and turns superiorly into the anterior portion of the temporalis muscle. The posterior deep temporal nerve, and the intermediate nerve if present, pass over the superior border of the lateral pterygoid close to the bone of the temporal fossa and enter the deep surface of the muscle. The posterior branch sometimes arises in common with the masseteric nerve.

**LATERAL PTERYGOID NERVE.** The lateral pterygoid nerve enters the deep surface of the muscle. It frequently arises in conjunction with the buccal nerve.

**BUCCAL NERVE.** The buccal nerve (buccinator nerve; long buccal nerve) (Fig. 12-11) passes between the two heads of the lateral pterygoid muscle to reach its superficial surface; it follows or penetrates the inferior part of the temporalis muscle and emerges from under the anterior border of the masseter muscle. It ramifies on the surface of the buccinator muscle, forming a plexus of communications with the buccal branches of the facial nerve; it supplies the skin of the cheek over this muscle and sends penetrating branches to supply the mucous membrane of the mouth and part of the gums in the same area.

**VARIATIONS.** The buccal nerve may supply a branch to the lateral pterygoid as it passes through that muscle, and frequently it gives off the anterior deep temporal nerve. It may arise from the trigemi-

nal ganglion, passing through its own foramen; it may be a branch of the inferior alveolar nerve; or it may be replaced by a branch of the maxillary nerve.

**POSTERIOR TRUNK**

The posterior division of the mandibular nerve is mainly sensory, but it has a small motor component. The following are its branches.

**AURICULOTEMPORAL NERVE.** The auriculotemporal nerve (Fig. 12-8) generally arises by two roots that join after encircling the middle meningeal artery close to the foramen spinosum. It runs posteriorly, deep to the lateral pterygoid muscle, along the medial side of the neck of the mandible, and it turns superiorly with the superficial temporal artery, between the auricula and the condyle of the mandible, under cover of the parotid gland. Escaping from beneath the gland, it passes over the root of the zygomatic arch and divides into superficial temporal branches (Fig. 12-18). The branches and communications of the auriculotemporal nerve are several.

The communications with the **facial nerve** (Fig. 12-11), usually two large communications, pass anteriorly from behind the neck of the mandible and join the facial nerve in the substance of the parotid gland at the posterior border of the masseter muscle. They carry sensory fibers that accompany the zygomatic, buccal, and mandibular branches of the facial nerve and supply the skin of these areas.

Communications with the **otic ganglion** (Fig. 12-20) join the roots of the auriculotemporal nerve close to their origin. They carry postganglionic parasympathetic fibers whose preganglionic fibers come from the glossopharyngeal nerve and supply the parotid gland with secretomotor fibers.

The **anterior auricular branches** (Fig. 12-11), usually two, supply the skin of the anterior superior part of the auricula, principally the helix and tragus.

The two branches to the **external acoustic meatus** (Fig. 12-11) enter the meatus between its bony and cartilaginous portions and supply the skin lining it; the upper one sends a filament to the tympanic membrane.

The **articular branches** consist of one or two twigs that enter the posterior part of the temporomandibular joint.

The **parotid branches** supply the parotid

gland, carrying the parasympathetic post-ganglionic fibers transmitted by the communication between the auriculotemporal nerve and the otic ganglion.

The **superficial temporal branches** accompany the superficial temporal artery to the vertex of the skull; they supply the skin of the temporal region and communicate with the facial and zygomaticotemporal nerves.

**LINGUAL NERVE.** The lingual nerve (Figs. 12-8; 12-12; 12-36) is at first deep to the lateral pterygoid muscle, running parallel with the inferior alveolar nerve and lying medial and anterior to it. It is frequently joined to the inferior alveolar nerve by a branch that may cross the maxillary artery. The chorda tympani nerve joins it here also. The lingual nerve runs between the medial pterygoid muscle and the mandible, and then crosses obliquely over the superior constrictor of

the pharynx and the styloglossus to reach the side of the tongue. It passes between the hyoglossus and the deep part of the submandibular gland. Finally, crossing the lateral side of the submandibular duct, it runs along the undersurface of the tongue to its tip, lying immediately beneath the mucous membrane (Fig. 12-12).

The **chorda tympani** (Figs. 12-8; 12-12), a branch of the facial nerve, joins the lingual nerve posteriorly at an acute angle, 1 or 2 cm from the foramen ovale. It carries special sensory fibers for taste and parasympathetic preganglionic fibers for the submandibular ganglion.

The communications with the **submandibular ganglion** are usually two or more short nerves by which the ganglion seems to be suspended (Fig. 12-12). The proximal nerves carry the preganglionic parasympa-

**FIG. 12-12.** Deep dissection of the region of the face viewed from its medial aspect, showing the pterygopalatine, otic, and submandibular ganglia and associated structures. (Redrawn from Töndury.)

thetic fibers communicated to the lingual by the chorda tympani. The distal communication contains postganglionic fibers for distribution to the sublingual gland.

Communications with the **hypoglossal nerve** (Fig. 12-36) form a plexus at the anterior margin of the hyoglossus muscle.

The **branches of distribution** supply the mucous membrane of the anterior two-thirds of the tongue, the adjacent mouth and gums, and the sublingual gland. The taste buds of the anterior two-thirds of the tongue are supplied by the fibers communicated through the chorda tympani.

**INFERIOR ALVEOLAR NERVE.** The inferior alveolar nerve (*inferior dental nerve*) (Fig. 12-11) accompanies the inferior alveolar artery, at first deep to the lateral pterygoid muscle and then between the sphenomandibular ligament and the ramus of the mandible, to the mandibular foramen. It enters the mandibular canal through the foramen, and passes anteriorly within the bone as far as the mental foramen, where it divides into two terminal branches.

The **mylohyoid nerve** (Fig. 12-8) leaves the inferior alveolar nerve just before it enters the mandibular foramen, and it continues inferiorly and anteriorly in a groove on the deep surface of the ramus of the mandible to reach the mylohyoid muscle. It supplies this muscle and crosses its superficial surface to reach the anterior belly of the digastric muscle (Fig. 12-8), which it also supplies.

The **dental branches** form a plexus within the bone and supply the molar and premolar teeth. Filaments enter the pulp canal of each root through the apical foramen and supply the pulp of the tooth.

The **incisive branch** is one of the terminal branches. It continues anteriorly within the bone, after the mental nerve separates from it, and forms a plexus that supplies the canine and incisor teeth.

The **mental nerve** (Fig. 12-11), the other terminal branch, emerges from the bone at the mental foramen and divides beneath the depressor anguli oris muscle into three branches: one is distributed to the skin of the chin; the other two, to the skin and mucous membrane of the lower lip. These branches communicate freely with branches of the facial nerve.

The otic and submandibular ganglia, although closely associated with the mandibular nerve, are not connected functionally,

and are described, therefore, with the nerves that supply them with preganglionic fibers: the otic ganglion with the glossopharyngeal nerve, and the submandibular with the facial nerve.

**VARIATIONS.** The inferior alveolar and lingual nerves may form a single trunk or they may have communications of variable size; the chorda tympani may appear to join the inferior alveolar nerve, with a later communication carrying the fibers to the lingual nerve. The inferior alveolar nerve is occasionally perforated by the maxillary artery. It may have accessory roots from other branches of the mandibular nerve or a separate root from the trigeminal ganglion. The mylohyoid nerve may communicate with the lingual nerve, and it has been described as sending filaments to the depressor anguli oris, the platysma, the submandibular gland, and the integument below the chin.

**TRIGEMINAL NERVE PAIN (TIC DOULOUREUX).** The trigeminal nerve is more frequently the seat of severe neuritic or neuralgic pain than any other nerve in the body. The pain of a localized infection or irritation may be confined to that area, but commonly this is not the case. Involvement of an internal branch is likely to cause severe distress in a related cutaneous area by referred pain. As a general rule the diffusion of pain over the branches of the nerve is confined to one of the main divisions, although in severe cases it may radiate over the other main divisions.

The commonest example of this condition is the neuralgia that is often associated with dental caries. Although the tooth itself may not appear to be painful, the most distressing referred pains are experienced, which are relieved at once by treatment of the affected tooth. With the ophthalmic nerve, severe supraorbital pain is commonly associated with acute glaucoma or with frontal or ethmoidal sinusitis. Malignant growths or empyema of the maxillary sinus and diseased conditions in the nasal cavity, as well as dental caries, may cause neuralgia of the second division. Pain in the mandibular division is likely to occur in the ear or other distribution of the auriculotemporal nerve, although the actual disease may involve one of the lower teeth or the tongue.

When a focus of infection or irritation cannot be found, as is all too frequently the case, various measures may be taken to interrupt the pain fibers. Local injection of alcohol into the painful nerve may give temporary relief, and injection of a main division close to the ganglion has been performed with a certain measure of success. The main divisions have been incised surgically, and the entire ganglion has been removed in intractable cases. In the latter operation, bleeding is likely to be dangerous and the nerves to the muscles of mastication may be paralyzed. In other operations, the motor root is spared by cutting the sensory root inside the cranium before it reaches the ganglion.

## VI. ABDUCENT NERVE

The **abducent nerve** (sixth nerve) (Fig. 12-6) supplies the rectus lateralis oculi muscle. Its superficial origin is in the furrow between the inferior border of the pons and the superior end of the pyramid of the medulla oblongata. It pierces the dura mater on the dorsum sellae of the sphenoid bone, runs through a notch below the posterior clinoid process, and traverses the cavernous sinus lateral to the internal carotid artery. It enters the orbit through the superior orbital fissure, superior to the ophthalmic vein, from which it is separated by a lamina of dura mater. After passing between the two heads of the rectus lateralis muscle, it enters its ocular surface.

**Communication with the sympathetic system** is by several filaments from the carotid and cavernous plexuses. Through a filament from the ophthalmic nerve, the abducent nerve communicates with the **trigeminal nerve**.

**RELATION OF ORBITAL NERVES TO CAVERNOUS SINUS.** Embedded in the lateral wall of the cavernous sinus, in order beginning with the most superior, are the oculomotor, trochlear, ophthalmic, and maxillary nerves (Fig. 12-13). The abducent nerve is suspended by connective tissue trabeculae within the sinus, lateral to the internal carotid artery and medial to the ophthalmic nerve. The maxillary nerve is related to the posterior portion of the sinus and it soon diverges from the other nerves. As the nerves approach the superior orbital fissure, the oculomotor and ophthalmic nerves divide into branches, and the abducent nerve approaches the others, so that their relative positions are considerably changed.

**FIG. 12-13.** Oblique section through the right cavernous sinus.

## VII. FACIAL NERVE

The **facial nerve** (seventh nerve) has two roots of unequal size (Fig. 12-14). The larger is the **motor root**; the smaller, lying between the motor root and the vestibulocochlear nerve, is called the **nervus intermedius** (nerve of Wrisberg<sup>1</sup>), and contains special sensory fibers for taste and parasympathetic fibers. The superficial origin of both roots is at the inferior border of the pons in the recess between the olive and the inferior cerebellar peduncle, the motor root being medial, the vestibulocochlear nerve lateral, and the nervus intermedius between.

The facial nerve is the motor nerve to the muscles of facial expression, to muscles in the scalp and external ear, and to the buccinator, platysma, stapedius, stylohyoid, and posterior belly of the digastric muscles. The sensory part supplies the anterior two-thirds of the tongue with taste, and parts of the external acoustic meatus, soft palate, and adjacent pharynx with general sensation. The parasympathetic part supplies secretomotor fibers for the submandibular, sublingual, lacrimal, nasal, and palatine glands.

From their superficial attachment, the two roots pass lateralward, with the vestibulocochlear nerve, into the internal acoustic meatus (Fig. 12-1). At the fundus of the meatus, the facial nerve separates from the vestibulocochlear nerve and enters the substance of the petrous portion of the temporal bone, through which it runs a serpentine course in the **facial canal** (*aqueductus Fallopii*<sup>2</sup>). At first it continues lateralward in the region between the cochlea and semicircular canals (Fig. 13-58); near the tympanic cavity it makes an abrupt bend posteriorly, runs in the medial wall of the cavity just above the oval window (Fig. 13-50), covered by a thin plate of bone that causes a slight prominence in the wall (Fig. 13-51), and then dips down beside the mastoid air cells to reach the stylomastoid foramen. Where it changes its course abruptly, there is an exaggeration of the bend into a U-shaped structure named the **geniculum**; at this point also, the two roots become fused and the nerve is swollen

<sup>1</sup>Heinrich August Wrisberg (1739-1808): A German anatomist (Göttingen).

<sup>2</sup>Gabriele Fallopius (1523-1552): An Italian anatomist (Padua).

FIG. 12-14. Plan of the facial and intermediate nerves and their communication with other nerves.

by the presence of the geniculate ganglion (Fig. 12-15).

As it emerges from the stylomastoid foramen, the nerve runs anteriorly in the substance of the parotid gland, crosses the external carotid artery, and divides at the posterior border of the ramus of the mandible into two primary branches—a superior branch, the temporofacial, and an inferior branch, the cervicofacial. Numerous branches come off the cervicofacial branch in a plexiform arrangement to form the **parotid plexus**; these are distributed over the head, face, and upper part of the neck, supplying the superficial muscles in these regions.

### Geniculate Ganglion

The **geniculate ganglion** (Fig. 12-15) is a small fusiform swelling of the geniculum, where the facial nerve bends abruptly backward at the hiatus of the facial canal. It is the sensory ganglion of the facial nerve. The central processes of its unipolar ganglion

cells reach the brain stem through the **nervus intermedius**; the majority of the peripheral processes pass to the taste buds of the anterior two-thirds of the tongue through the chorda tympani and lingual nerves; many peripheral processes pass through the greater superficial petrosal and lesser palatine nerves to the soft palate; and a smaller number join the auricular branch of the vagus nerve to supply the skin of the external acoustic meatus and mastoid process (Foley et al., 1946).

The **glossopalatine nerve** is the name given by some authors (Hardesty, 1933) to that portion of the facial nerve contributed by the **nervus intermedius**. It comprises, therefore, the sensory part, including the geniculate ganglion, the chorda tympani, and greater petrosal nerve; and the parasympathetic part, including the submandibular and pterygopalatine ganglia and their branches. Although this separation is suggested by the similarity between this complex and the glossopharyngeal nerve, it has not been generally adopted.

### Communications of the Facial Nerve

In the internal acoustic meatus, communications with the **vestibulocochlear nerve** probably contain fibers that leave the facial nerve, run with the vestibulocochlear nerve for a short distance, and return to the facial nerve.

At the geniculate ganglion, the facial nerve communicates with the **otic ganglion** by filaments that join the lesser petrosal nerve, and with the **sympathetic fibers** on the middle meningeal artery (external superficial petrosal nerve).

In the facial canal, just before it leaves the stylomastoid foramen, the facial nerve communicates with the **auricular branch of the vagus** as the latter runs across it in the substance of the bone.

After its exit from the stylomastoid foramen, the facial nerve communicates with the **glossopharyngeal nerve**, the **vagus nerve**, and the **great auricular nerve** from the cervical plexus. The **auriculotemporal nerve** from the mandibular division of the trigeminal usually sends two large communications that pass anteriorly from behind the neck of the mandible to join the facial nerve in the substance of the parotid gland (Fig. 12-11). They carry sensory fibers that accompany the terminal zygomatic, buccal, and mandibular branches to the skin of these areas.

Peripheral branches of the facial nerve communicate behind the ear, with the **lesser occipital nerve**; on the face, with **trigeminal branches**; and in the neck, with the **cervical cutaneous nerve**.

### Branches of Facial Nerve from the Geniculate Ganglion

#### GREATER PETROSAL NERVE

The **greater petrosal nerve** (greater superficial petrosal nerve) arises from the geniculate ganglion (Fig. 12-15), and after a short course in the bone, it emerges through the hiatus of the facial canal into the middle cranial fossa. It runs rostralward beneath the dura mater and the trigeminal ganglion in a sulcus on the anterior surface of the petrous portion of the temporal bone, passes superior to the cartilage of the auditory tube (which fills the foramen lacerum), crosses the lateral side of the internal carotid artery, and unites with the deep petrosal nerve to

Fig. 12-15. The geniculate ganglion and facial nerve in the temporal bone.

form the nerve of the pterygoid canal (Vidian nerve) (Figs. 12-9; 12-12). The greater petrosal nerve is a mixed nerve, containing sensory and parasympathetic fibers. The parasympathetic fibers, from the *nervus intermedius*, become the motor root of the pterygopalatine ganglion. The bulk of the nerve consists of sensory fibers, which are the peripheral processes of cells in the geniculate ganglion and are distributed to the soft palate through the lesser palatine nerves, with a few filaments to the auditory tube.

#### Nerve of Pterygoid Canal

The **nerve of the pterygoid canal** (Vidian nerve) (Fig. 12-9), formed by the union of the greater petrosal and deep petrosal nerves at the foramen lacerum, enters the posterior opening of the pterygoid canal with the corresponding artery and is joined by a small *ascending sphenoidal branch* from the otic ganglion. The bony wall of the canal commonly causes a ridge in the floor of the sphenoidal sinus, and while the nerve is in the canal it gives off one or two filaments for the mucous membrane of the sinus. From the anterior opening of the canal, the nerve crosses the pterygopalatine fossa and enters the pterygopalatine ganglion.

#### Pterygopalatine Ganglion

The **pterygopalatine ganglion** (sphenopalatine ganglion; Meckel's ganglion) (Figs. 12-9; 12-12) is deeply placed in the pterygopalatine fossa, just inferior to the maxillary nerve as the latter crosses the fossa close to the pterygopalatine foramen. It is triangular or heartshaped and about 5 mm long. It is embedded in the fibrous tissue between the neighboring bones and is closely attached to the pterygopalatine branches of the maxillary division of the trigeminal nerve. It is a parasympathetic ganglion relaying chiefly

**FIG. 12-16.** Autonomic connections of the pterygopalatine and superior cervical ganglia. Parasympathetic blue; sympathetic red.

secretomotor impulses from the facial nerve (Fig. 12-16).

The **parasympathetic root** (visceral efferent) of the pterygopalatine ganglion is the greater petrosal nerve, and its continuation, the nerve of the pterygoid canal. The fibers are preganglionic parasympathetic fibers, which leave the brain stem in the nervus intermedius.

**COMMUNICATIONS OF THE PTERYGOPALATINE GANGLION. Maxillary Nerve.** Two short trunks from the maxillary nerve, the pterygopalatine nerves, are commonly called the sensory root of the ganglion although they have no such functional connection with it. They contain mainly sensory fibers from the trigeminal ganglion that pass through or beside the pterygopalatine ganglion without synapses and continue on their way to the mucous membrane of the nasal cavity and

palate. These trunks are important communications for the ganglion, however, since they are traversed by the postganglionic fibers of distribution on their way to the maxillary nerve, whence they reach the lacrimal gland and the small glands of the nasal cavity and palate.

**Deep Petrosal Nerve** The deep petrosal nerve is commonly called the sympathetic root of the pterygopalatine ganglion, although it is merely a communication between the ganglion and the sympathetic system. It contains postganglionic fibers from the superior cervical sympathetic ganglion, by way of the carotid plexus, and passes through the pterygopalatine ganglion without synapses and accompanies the branches of the pterygopalatine nerves (trigeminal branches) to their destination in the mucous membrane of the nasal cavity and palate.

**BRANCHES FROM THE PTERYGOPALATINE GANGLION.** The branches of distribution from the pterygopalatine ganglion, containing the postganglionic fibers of the cells within the ganglion, are not independent nerves for the most part, but find their way to their destinations by accompanying other nerves, mainly the branches of the maxillary nerve.

The fibers for the **lacrimal gland** pass back to the main trunk of the maxillary nerve through the pterygopalatine nerves. They leave the maxillary through the zygomatic and zygomaticotemporal nerves, pass through a communication between the latter and the lacrimal nerve in the orbit, and are then distributed to the gland (Fig. 12-6).

Fibers for the **small glands** of the mucous membrane of the **nasal cavity**, **pharynx**, and **palate** join the greater and lesser palatine nerves, the posterior superior nasal branches, and the pharyngeal branch, and are distributed with them.

#### *Branches of Facial Nerve Within the Facial Canal*

#### **NERVE TO STAPEDIUS MUSCLE**

The **nerve to the stapedius muscle** arises from the facial nerve as it passes downward in the posterior wall of the tympanum. It reaches the muscle through a minute opening in the base of the pyramid (see Middle Ear, Chapter 13).

#### **CHORDA TYMPANI NERVE**

The **chorda tympani nerve** (Figs. 12-8; 12-12) arises from the part of the facial nerve that runs vertically downward in the posterior wall of the tympanum just before it reaches the stylomastoid foramen. Entering its own canal in the bone about 6 mm above the stylomastoid foramen, the chorda passes back cranialward almost parallel with the facial nerve but diverges toward the lateral wall of the tympanum. It emerges through an aperture in the posterior wall of the tympanum (*iter chordae posterius*) between the base of the pyramid and the attachment of the tympanic membrane. It runs horizontally along the lateral wall of the tympanum covered by the thin mucous membrane, and, lying against the tympanic membrane, it crosses the attached manubrium of the mal-

leus (Fig. 13-49). It leaves the tympanic cavity near the anterior border of the membrane through the *iter chordae anteriorius*, traverses a canal in the petrotympanic fissure (canal of Huguier<sup>1</sup>), and emerges from the skull on the medial surface of the spine of the sphenoid bone. After crossing the spine, usually in a groove, and being joined by a small communication from the otic ganglion, it unites with the lingual nerve at an acute angle between the medial and lateral pterygoid muscles.

The bulk of the fibers of the chorda tympani are special visceral afferents for taste, which are distributed with the branches of the lingual nerve to the anterior two-thirds of the tongue. It also contains preganglionic parasympathetic fibers (secretomotor) from the nervus intermedius, which terminate in synapses with cells in the submandibular ganglion (Foley, 1945).

**SUBMANDIBULAR GANGLION.** The **submandibular ganglion** (submaxillary ganglion) (Figs. 12-8; 12-12) is a small mass, 2 to 5 mm in diameter, situated above the deep portion of the submandibular gland on the hyoglossus muscle, near the posterior border of the mylohyoid muscle and suspended from the lower border of the lingual nerve by two filaments approximately 5 mm long. The proximal filament is the **parasympathetic root**, which conveys fibers originating in the nervus intermedius and is communicated to the lingual nerve by the chorda tympani. These are preganglionic visceral efferent fibers (secretomotor) whose postganglionic fibers innervate the submandibular, sublingual, lingual, and neighboring small salivary glands (Fig. 12-17).

The **branches of distribution** are (a) five or six filaments distributed to the submandibular gland and its duct, (b) to the small glands about the floor of the mouth, and (c) the distal filament attaching the ganglion to the lingual nerve, which communicates the fibers distributed to the sublingual and small lingual glands with the terminal branches of the lingual nerve. Small groups of ganglion cells are constantly found in the stroma of the submandibular gland, usually near the larger branches of the duct, and functionally are considered a part of the submandibular ganglion.

<sup>1</sup>Pierre Charles Huguier (1804-1873): A French surgeon (Paris).

**FIG. 12-17.** Autonomic connections of the submandibular and superior cervical ganglia. Parasympathetic blue; sympathetic red.

A communication with the sympathetic bundles on the facial artery has been called the sympathetic root of the ganglion, but the fibers are postganglionic and have no synapses in the ganglion.

Visceral afferent fibers passing through the root to the lingual and thence to the chorda tympani have been called the sensory root, but they have no synapses in the ganglion and their cell bodies are in the geniculate ganglion.

#### *Branches of Facial Nerve in the Face and Neck*

**POSTERIOR AURICULAR NERVE.** The posterior auricular nerve (Fig. 12-18) arises close to the stylomastoid foramen and runs cranialward anterior to the mastoid process; here it is joined by a filament from the auricular branch of the vagus, and communicates

with the posterior branch of the great auricular nerve and with the lesser occipital nerve. Between the external acoustic meatus and the mastoid process it divides into auricular and occipital branches. The auricular branch supplies the auricularis posterior and the intrinsic muscles on the cranial surface of the auricle. The occipital branch, the larger of the two, passes backward along the superior nuchal line of the occipital bone and supplies the occipitalis muscle.

**DIGASTRIC BRANCH.** The digastric branch arises close to the stylomastoid foramen, and divides into several filaments, which supply the posterior belly of the digastric muscle.

**STYLOHYOID BRANCH.** The stylohyoid branch frequently arises in conjunction with the digastric branch; it is long and slender, and enters the stylohyoid muscle near its middle.

**PAROTID PLEXUS.** The terminal portion of

Fig. 12-18. The nerves of the scalp, face, and side of neck.

the facial nerve, within the substance of the parotid gland, divides into a temporofacial and a cervicofacial division which in turn, either within the gland or after leaving it, break up into a plexus and supply the facial muscles in different regions.

**Temporal Branches.** The temporal branches (Fig. 12-18) cross the zygomatic arch to the temporal region, supplying the auriculares anterior and superior. They communicate with the zygomaticotemporal branch of the maxillary nerve and with the auriculotemporal branch of the mandibular division of the trigeminal nerve. The more anterior branches supply the frontalis, the orbicularis oculi, and the corrugator muscles and join the supraorbital and lacrimal branches of the ophthalmic nerve.

**Zygomatic Branches.** The zygomatic branches (malar branches) run across the face in the region of the zygomatic arch to the lateral angle of the orbit, where they supply the orbicularis oculi, and communicate with filaments from the lacrimal nerve of the ophthalmic division and the zygomaticofacial branch of the maxillary division of the trigeminal nerve. The lower zygomatic branches commonly join the deep buccal branches and assist in forming the infraorbital plexus.

**Buccal Branches.** The buccal branches (infraorbital branches), larger than the rest, pass horizontally rostralward to be distributed inferior to the orbit and around the mouth. The superficial branches run beneath the skin and superficial to the muscles

of the face, which they supply; some are distributed to the procerus muscle, communicating at the medial angle of the orbit with the infratrochlear and nasociliary branches of the ophthalmic nerve. The deep branches, commonly reinforced by zygomatic branches, pass deep to the zygomaticus and the levator labii superioris muscles, supplying them and forming an infraorbital plexus with the infraorbital branch of the maxillary division of the trigeminal nerve (Fig. 12-18). These branches also supply the small muscles of the nose. The more inferior deep branches supply the buccinator and orbicularis oris muscles, and communicate with filaments of the buccal branch of the mandibular division of the trigeminal nerve.

**Mandibular Branch.** The mandibular branch (*r. marginalis mandibulae*) passes rostralward deep to the platysma and depressor anguli oris supplying the muscles of the lower lip and chin and communicating with the mental branch of the inferior alveolar nerve.

**Cervical Branch.** The cervical branch (*r. colli*) runs rostralward deep to the platysma, which it supplies, and forms a series of arches across the side of the neck over the suprahyoid region. One branch joins the cervical cutaneous nerve from the cervical plexus.

## VIII. VESTIBULOCOCHLEAR NERVE

The vestibulocochlear nerve (*n. statoacusticus*; *n. octavius*; eighth nerve) (Fig. 11-62) consists of two distinct sets of fibers, the cochlear and vestibular nerves, which differ in their peripheral endings, central connections, functions, and time of myelination. These two portions of the vestibulocochlear nerve are joined into a common trunk that enters the internal acoustic meatus with the facial nerve (Fig. 12-15). Centrally, the vestibulocochlear nerve divides into a lateral (cochlear) root and a medial (vestibular) root. As it passes distally in the internal auditory meatus, it divides into the various branches, which are distributed to the receptor areas in the membranous labyrinth (see Chapter 13). Both divisions of this nerve are sensory and the fibers arise from bipolar ganglion cells.

**COCHLEAR NERVE.** The cochlear nerve or root, the nerve of hearing, arises from bipolar cells in the spiral ganglion of the cochlea, situated near the inner edge of the osseous spiral lamina. The peripheral fibers pass to the organ of Corti.<sup>1</sup> The central fibers pass through the modiolus and then through the foramina of the tractus spiralis foraminosus or through the foramen centrale into the lateral or outer end of the internal acoustic meatus. The nerve passes along the internal acoustic meatus with the vestibular nerve and across the subarachnoid space, just above the flocculus, almost directly medialward toward the inferior peduncle to terminate in the cochlear nuclei.

The cochlear nerve is placed lateral to the vestibular root. Its fibers end in two nuclei: one, the ventral cochlear nucleus, lies immediately in front of the inferior cerebellar peduncle; the other, the dorsal cochlear nucleus, tuberculum acusticum, somewhat lateral to it (see Chapter 11).

**VESTIBULAR NERVE.** The vestibular nerve or root, the nerve of equilibration, arises from bipolar cells in the vestibular ganglion (*ganglion of Scarpa*<sup>2</sup>) which is situated in the superior part of the lateral end of the internal acoustic meatus. The peripheral fibers divide into three branches: the superior branch passes through the foramina in the area vestibularis superior and ends in the utricle and in the ampullae of the anterior and lateral semicircular ducts; the fibers of the inferior branch traverse the foramina in the area vestibularis inferior and end in the saccule; the posterior branch runs through the foramen singulare and supplies the ampulla of the posterior semicircular duct.

The fibers of the vestibular nerve enter the medulla oblongata, pass between the inferior cerebellar peduncle and the spinal tract of the trigeminal nerve, and bifurcate into ascending and descending branches. The descending branches form the spinal root of the vestibular nerve and terminate in the associated nucleus. The ascending branches pass to the medial, lateral, and superior vestibular nuclei, and to the nucleus fastigii and the vermis of the cerebellum.

<sup>1</sup>Alfonso Corti (1822-1888): An Italian anatomist (born in Sardinia, worked in Germany).

<sup>2</sup>Antonio Scarpa (1747-1832): An Italian anatomist and surgeon (Pavia).

## IX. GLOSSOPHARYNGEAL NERVE

The **glossopharyngeal nerve** (ninth nerve) (Fig. 12-22), as its name implies, is distributed to the tongue and pharynx. It is a mixed nerve, its sensory fibers being both visceral and somatic, and its motor fibers both general and special visceral efferents. The somatic afferent fibers supply the mucous membrane of the pharynx, fauces, palatine tonsil, and posterior part of the tongue; special visceral afferents supply the taste buds of the posterior part of the tongue; general visceral afferents supply the blood pressure receptors of the carotid sinus. The special visceral efferent fibers supply the stylopharyngeus muscle; the general visceral efferents are mainly secretomotor for the parotid and small glands in the mucous membrane of the posterior part of the tongue and neighboring pharynx. The superficial origin is by three or four rootlets in series with those of the vagus nerve, attached to the superior part of the medulla oblongata in the groove between the olive and the inferior peduncle.

From its superficial origin, the nerve passes lateralward across the flocculus to the jugular foramen, through which it passes, lateral and anterior to the vagus and accessory nerves (Fig. 12-22), in a separate sheath of dura mater and lying in a groove on the lower border of the petrous portion of the temporal bone. After its exit from the skull, it runs anteriorly between the internal jugular vein and the internal carotid artery, superficial to the latter vessel and posterior to the styloid process and its muscles. It follows the posterior border of the stylopharyngeus muscle for 2 or 3 cm, then curves across its superficial surface to the posterior border of the hyoglossus muscle, where it penetrates more deeply to be distributed to the palatine tonsil, the mucous membrane of the fauces and base of the tongue, and the glands of that region. The portion of the nerve that lies in the jugular foramen has two enlargements, the superior and the inferior ganglia.

The **superior ganglion** (jugular ganglion) is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is very small, may be absent, and is usually regarded as a detached portion of the inferior ganglion.

The **inferior ganglion** (petrous ganglion) is situated in a depression in the lower border of the petrous portion of the temporal bone. These ganglia contain the cell bodies for the sensory fibers of the nerve (Fig. 12-21).

### *Communications of Glossopharyngeal Nerve*

(1) The communications with the **vagus nerve** are two filaments, one joining the auricular branch, the other the superior ganglion. (2) The superior cervical **sympathetic** ganglion communicates with the inferior ganglion. (3) The communication with the **facial nerve** is between the trunk of the glossopharyngeal nerve below the inferior ganglion and the facial nerve after its exit from the stylomastoid foramen; it perforates the posterior belly of the digastric muscle.

### *Branches of Glossopharyngeal Nerve*

#### **TYMPANIC NERVE**

The **tympanic nerve** (nerve of Jacobson) (Fig. 12-19) supplies parasympathetic fibers to the parotid gland through the otic ganglion and sensory fibers to the mucous membrane of the middle ear. It arises from the inferior ganglion and enters a small canal through an opening in the bony ridge that separates the carotid canal from the jugular fossa on the inferior surface of the petrous portion of the temporal bone. After a short cranialward course in the bone, it enters the tympanic cavity by an aperture in its floor near the medial wall. It continues upward in a groove on the surface of the promontory (Fig. 13-50), helps to form the tympanic plexus, reenters a canaliculus at the level of the processus cochleariformis, passes internal to the semicanal for the tensor tympani, and continues as the lesser petrosal nerve (Rosen, 1950).

**TYMPANIC PLEXUS.** The tympanic plexus lies in grooves on the surface of the promontory and is formed by the junction of the tympanic and caroticotympanic nerves. The **caroticotympanic nerves**, **superior** and **inferior**, are communications from the carotid plexus of the sympathetic, which enter the tympanic cavity by perforating the wall of the carotid canal. The plexus communicates

**FIG. 12-19.** Autonomic connections of the otic and superior cervical ganglia. Parasympathetic blue; sympathetic red.

with the greater petrosal nerve by a filament that passes through an opening on the labyrinthine wall, in front of the fenestra vestibuli.

**Sensory branches** are distributed through the plexus to the mucous membrane of the fenestra ovalis, fenestra rotunda, tympanic membrane, auditory tube, and mastoid air cells.

The **lesser petrosal nerve** (Figs. 12-9; 12-20) is the terminal branch or continuation of the tympanic nerve beyond the plexus. After penetrating the bone medial to the tensor tympani muscle, it emerges into the cranial cavity on the superior surface of the petrous portion of the temporal bone, immediately lateral to the hiatus of the facial canal. It leaves the cranial cavity again through the

fissure between the petrous portion and the great wing of the sphenoid, or through a small opening in the latter bone, and terminates in the otic ganglion as its visceral motor or parasympathetic root. In the canal it is joined by a filament from the geniculate ganglion of the facial nerve.

#### OTIC GANGLION

The **otic ganglion** (Figs. 12-12; 12-20) is a flat, oval, or stellate ganglion, 2 to 4 mm in diameter, closely approximated to the medial surface of the mandibular division of the trigeminal, immediately outside of the foramen ovale, and it has the origin of the medial pterygoid nerve embedded in it. It is lateral to the cartilaginous portion of the auditory tube, anterior to the middle meningeal artery, and posterior to the origin of the tensor veli palatini muscle.

The **root of the otic ganglion**, which is **parasympathetic**, is the lesser petrosal nerve. It contains preganglionic fibers from the nucleus salivatorius inferior in the medulla oblongata, principally through the glossopharyngeal nerve but probably partly also through the facial nerve.

#### COMMUNICATIONS OF THE OTIC GANGLION.

A communication with the **sympathetic** network on the middle meningeal artery has been called the sympathetic root of the ganglion, but these fibers are already postganglionic and pass through the ganglion without synapses.

A communication with the **medial pterygoid nerve** has been described as a motor root, and the continuation of the fibers to the tensor veli palatini and tensor tympani muscles has been described as branches of the ganglion, but they are trigeminal fibers that pass through the ganglion.

A communication with the **mandibular nerve** has been called a sensory root, but the fibers have no functional connection with the ganglion. A slender filament, the **sphenoidal branch**, connects with the nerve of the pterygoid canal, and a small branch communicates with the **chorda tympani**.

**BRANCHES OF DISTRIBUTION OF THE OTIC GANGLION.** The postganglionic fibers arising in the otic ganglion pass mainly through a communication with the auriculotemporal nerve and are distributed with its branches

**FIG. 12-20.** The otic ganglion and its branches.

to the **parotid gland**. Other filaments probably accompany other nerves to reach small glands in the mouth and pharynx.

## CAROTID SINUS NERVE

The **carotid sinus nerve** (nerve of Hering<sup>1</sup>) (Fig. 12-21) arises from the main trunk of the glossopharyngeal nerve just beyond its emergence from the jugular foramen; it communicates with the nodose ganglion or the pharyngeal branch of the vagus nerve near its origin. Its continuation or principal branch runs down the anterior surface of the internal carotid artery to the carotid bifurcation, and it terminates in the wall of the dilated portion of the artery—the carotid sinus—supplying it with afferent fibers for its blood pressure receptors. It has a rather constant branch that joins the intercarotid plexus, formed principally by vagus and sympathetic branches, or it communicates with these nerves independently and reaches the carotid body. Glossopharyngeal fibers may traverse the plexus and its branches to the carotid body on their way to the carotid sinus (Sheehan et al., 1941). Its functional association with the carotid body is questionable.

<sup>1</sup>Heinrich Ewald Hering (1866-1948): A German physiologist (Cologne).

## PHARYNGEAL BRANCHES

The **pharyngeal branches** are three or four filaments that join pharyngeal branches of the vagus and sympathetic nerves opposite the constrictor pharyngis medius muscle to form the **pharyngeal plexus** (Fig. 12-21). Branches from the plexus penetrate the muscular coat of the pharynx and supply its muscles and mucous membrane; the exact contribution of the glossopharyngeal nerve is uncertain.

### BRANCH TO STYLOPHARYNGEUS

The **branch** to the **stylopharyngeus** is the only muscular branch of the glossopharyngeal nerve.

## TONSILLAR BRANCHES

The **tonsillar branches** supply the palatine tonsil, forming around it a network from which filaments are distributed to the soft palate and fauces, where they communicate with the lesser palatine nerves.

## LINGUAL BRANCHES

The **lingual branches** are two in number; one supplies the vallate papillae with afferent fibers for taste, and general afferents to the mucous membrane at the base of the

**FIG. 12-21.** Carotid sinus nerve, carotid body, internal carotid artery, and neighboring cranial, spinal, and sympathetic nerve connections. Diagrammatic.

tongue; the other supplies the mucous membrane and glands of the posterior part of the tongue, and communicates with the lingual nerve.

**CLINICAL COMMENT.** Neuralgic pain or "tic douloureux" of the glossopharyngeal nerve occurs in the ear, throat, base of the tongue, rim of the palate, and the lower lateral and posterior part of the pharynx. The most common trigger zone is the tonsillar fossa (Pastore and Meredith, 1949).

## X. THE VAGUS NERVE

The **vagus nerve** (tenth nerve; pneumogastric nerve) (Figs. 12-22; 12-37), named from its wandering course, is the longest of the cranial nerves and has the most extensive distribution, passing through the neck and thorax into the abdomen. It has both

somatic and visceral afferent fibers, and general and special visceral efferent fibers. The somatic sensory fibers supply the skin of the posterior surface of the external ear and the external acoustic meatus; the visceral afferent fibers supply the mucous membrane of the pharynx, larynx, bronchi, lungs, heart, esophagus, stomach, intestines, and kidney. General visceral efferent fibers (parasympathetic) are distributed to the heart, and supply the nonstriated muscle and glands of the esophagus, stomach, trachea, bronchi, biliary tract, and most of the intestine. Special visceral efferent fibers supply the voluntary muscles of the larynx, pharynx, and palate (except the tensor), but most of the latter fibers originate in the cranial part of the accessory nerve.

The superficial origin of the vagus is composed of eight or ten rootlets attached to the medulla oblongata in the groove between

**Fig. 12-22.** Course and distribution of the glossopharyngeal, vagus, and accessory nerves.

the olive and the inferior peduncle, inferior to those of the glossopharyngeal nerve and superior to those of the accessory nerve. The rootlets unite into a flat cord that passes beneath the flocculus of the cerebellum to the

jugular foramen. The nerve leaves the cranial cavity through this opening, accompanied by the accessory nerve and contained in the same dural sheath, but separated by a septum from the glossopharyngeal nerve, which lies anteriorly. This portion of the vagus has two enlargements, the superior and inferior ganglia, which are the **sensory ganglia** of the nerve.

**SUPERIOR GANGLION.** The **superior ganglion** (g. of the root; jugular ganglion) (Fig. 12-21) is a spherical swelling, about 4 mm in diameter, of the vagus nerve as it lies in the jugular foramen. The central processes of its unipolar (sensory) ganglion cells enter the medulla, usually in three or four large independent rootlets, slightly dorsal to the motor rootlets. Most of the peripheral processes of the ganglion cells enter the auricular branch of the vagus, but a few probably are distributed with the pharyngeal branches.

**INFERIOR GANGLION.** The **inferior ganglion** (g. of the trunk; nodose ganglion) (Fig. 12-23) forms a fusiform swelling about 2.5 cm long on the vagus nerve after its exit from the jugular foramen and about 1 cm distal to the superior ganglion. The central processes of its unipolar (sensory) cells pass through the superior ganglion without traversing the region occupied by cells, and frequently accompany motor fibers in the rootlets for a short distance but enter the medulla slightly dorsal to them, in line with the superior rootlets. Some of the peripheral processes of the ganglion cells make up the internal ramus of the superior laryngeal nerve, and the rest are distributed with other branches of the vagus to the larynx, trachea, bronchi, esophagus, and other thoracic and abdominal viscera.

### *Communications of the Vagus Nerve*

At the superior ganglion, several delicate filaments communicate (1) with the cranial portion of the **accessory nerve**; (2) with the inferior ganglion of the **glossopharyngeal nerve**; (3) with the **facial nerve** by means of the auricular branch; and (4) with the superior cervical ganglion of the **sympathetic system** (jugular nerve).

The cranial part of the **accessory nerve** joins the vagus just proximal to the inferior ganglion. It is the source of the greater part of the fibers in the motor branches of the vagus to the pharynx and larynx.

**FIG. 12-23.** Dorsal view of the pharynx and associated nerves and blood vessels after removal of the cervical vertebrae and part of the occipital bone. (Redrawn from Töndury.)

At the inferior ganglion, communication is (1) with the **hypoglossal nerve**, (2) with the superior cervical **sympathetic ganglion**, and (3) with the loop between the **first and second cervical spinal nerves**.

The resulting **vagus nerve trunk**, after it

has been joined by the cranial part of the accessory nerve just distal to the inferior ganglion, passes vertically down the neck within the carotid sheath, deep to and between the internal jugular vein and the internal and common carotid arteries. Beyond the

root of the neck the course of the nerve differs on the two sides of the body.

The **right vagus nerve** crosses the first part of the subclavian artery, lying superficial to it and between it and the brachiocephalic vein (Fig. 12-24). It continues along the side of the trachea to the dorsal aspect of the root of the lung, where it spreads out in the posterior pulmonary plexus (Fig. 12-25). Below this plexus, it splits into cords that enter into the formation of the plexus on the dorsal aspect of the esophagus. After sending communications to the left vagus, these cords unite with each other and with com-

munications from the left vagus to form a single trunk, the posterior vagus nerve, before passing through the esophageal hiatus in the diaphragm (Fig. 12-25). Below the diaphragm, the posterior vagus continues along the lesser curvature of the stomach on its posterior surface for a short distance and divides into a celiac and several gastric branches.

The **left vagus** enters the thorax between the left carotid and subclavian arteries, deep to the left brachiocephalic vein (Fig. 12-37). It crosses the left side of the arch of the aorta (Fig. 12-24), angling dorsally in its caudal-

**FIG. 12-24.** The mediastinal organs and the roots of the lungs after removal of the heart and pericardium. (Redrawn from Töndury.)

**FIG. 12-25.** Dorsal view of the mediastinal structures and roots of the lungs, after removal of the vertebral column, ribs, and thoracic aorta. (Redrawn from Töndury.)

ward course. It passes between the aorta and the left pulmonary artery just distal to the ligamentum arteriosum, and reaches the dorsal aspect of the root of the lung, where it flattens into the posterior pulmonary plexus (Fig. 12-25). It reaches the esophagus as a

variable number of strands; these follow the ventral aspect of the esophagus, send communications to the right vagus, and usually unite with each other and with substantial communications from the right vagus to form a single trunk, the *anterior vagus*

nerve, before passing through the diaphragm. Below the diaphragm, the anterior vagus nerve, on the anterior aspect of the stomach, divides into an hepatic and several gastric branches (Jackson, 1949).

### *Branches in the Jugular Fossa*

**MENINGEAL BRANCH.** The meningeal branch (*dural branch*) is a recurrent filament that arises at the superior ganglion and is distributed to the dura mater in the posterior cranial fossa.

**AURICULAR BRANCH.** The auricular branch (nerve of Arnold<sup>1</sup>) arises from the superior ganglion and soon communicates by a filament with the inferior ganglion of the glossopharyngeal nerve. It passes posterior to the internal jugular vein, and when it reaches the lateral wall of the jugular fossa, it enters the mastoid canaliculus, which crosses the facial canal in the bone about 4 mm superior to the stylomastoid foramen and communicates with the facial nerve. It is a somatic afferent nerve and it reaches the surface by passing through the tympanomastoid fissure. It divides into two branches: (a) one joins the posterior auricular nerve, and (b) the other is distributed to the skin of the back of the auricle and to the posterior part of the external acoustic meatus.

### *Branches of the Vagus Nerve in the Neck*

**PHARYNGEAL BRANCHES.** The pharyngeal branches, usually two, arise at the upper part of the inferior ganglion; they contain sensory fibers from the ganglion and motor fibers from the communication with the accessory nerve. They pass across the internal carotid artery to the superior border of the constrictor pharyngis medius where they divide into several bundles that join branches of the glossopharyngeal, sympathetic, and external branch of the superior laryngeal nerves to form the **pharyngeal plexus** (Fig. 12-21).

Through the plexus, branches are distributed to the muscles and mucous membrane of the **pharynx**, and to the muscles of the **soft palate**, except the tensor veli palatini.

The nerves to the **carotid body** are filaments from the pharyngeal and possibly from the superior laryngeal branches, which join with similar filaments from the glossopharyngeal nerve and the superior cervical sympathetic ganglion to form the intercarotid plexus between the internal and external carotid arteries at the bifurcation. The vagus fibers are visceral afferents that terminate in the carotid body, which is a chemoreceptor sensitive to changes in oxygen tension of the blood. This is located at the carotid bifurcation (Sheehan et al., 1941).

**SUPERIOR LARYNGEAL NERVE.** The superior laryngeal nerve (Fig. 12-22) arises near the lower end of the inferior ganglion and passes caudalward and medialward deep to the internal carotid artery and along the pharynx toward the superior cornu of the thyroid cartilage. It has a communication with the superior cervical sympathetic ganglion and may contribute to the intercarotid plexus. It terminates by dividing into a smaller external and a larger internal branch.

The **external branch** (Fig. 12-22) continues caudalward beside the larynx, deep to the sternothyroid muscle and supplies motor fibers to the cricothyroid muscle and part of the constrictor pharyngis inferior. It contributes fibers to the pharyngeal plexus and communicates with the superior sympathetic cardiac nerve.

The **internal branch** swings anteriorly to reach the thyrohyoid membrane, which it pierces with the superior laryngeal artery. It supplies sensory fibers to the mucous membrane and parasympathetic secretomotor fibers to the associated glands through branches to the epiglottis, base of the tongue, aryepiglottic fold, and the larynx as far caudalward as the vocal folds. A filament passes caudalward beneath the mucous membrane on the inner surface of the thyroid cartilage and joins the recurrent nerve (Fig. 12-23).

**SUPERIOR CARDIAC BRANCHES.** Two or three superior cardiac branches arise from the vagus at the superior and inferior parts of the neck. The superior branches are small and communicate with the cardiac branches of the sympathetic. They can be traced to the deep part of the cardiac plexus. The inferior branch arises at the root of the neck just cra-

<sup>1</sup>Philipp Friedrich Arnold (1803-1890): A German anatomist (Zurich, Freiburg, Tübingen, and Heidelberg).

nial to the first rib. On the right side it passes ventral or lateral to the brachiocephalic artery and joins the deep part of the cardiac plexus. On the left side it passes across the left side of the arch of the aorta and joins the superficial part of the cardiac plexus.

**RECURRENT NERVE.** The recurrent nerve (inferior or recurrent laryngeal nerve) (Fig. 12-25), as its name implies, arises far caudally and runs back cranialward in the neck to its destination, the muscles of the larynx. The origin and early part of its course are different on the two sides. **On the right side,** it arises in the root of the neck, as the vagus crosses superficial to the first part of the subclavian artery. It loops under the arch of this vessel and passes dorsal to it to the side of the trachea and esophagus (Fig. 12-74). **On the left side,** the recurrent nerve arises in the cranial part of the thorax, as the vagus crosses the left side of the arch of the aorta (Fig. 12-75). Just distal to the ligamentum arteriosum, it loops under the arch and passes around it to the side of the trachea. The further course on the two sides is similar; it passes deep to the common carotid artery and along the groove between the trachea and esophagus, medial to the overhanging deep surface of the thyroid lobe. Here it comes into close relationship with the terminal portion of the inferior thyroid artery. It runs under the caudal border of the constrictor pharyngis inferior muscle, enters the larynx through the cricothyroid membrane deep to the articulation of the inferior cornu of the thyroid with the cricoid cartilage, and is distributed to all the muscles of the larynx except the cricothyroid. Its branches are as follows:

**Cardiac branches** are given off as the nerve loops around the subclavian artery or the aorta. These are described below as the inferior cardiac branches of the vagus.

**Tracheal and esophageal branches,** more numerous on the left than on the right, are distributed to the mucous membranes and muscular coats (Fig. 12-23).

**Pharyngeal branches** are filaments to the constrictor pharyngis inferior.

Sensory and secretomotor filaments, which reach the recurrent through the communication with the internal branch of the superior laryngeal, supply the mucous membrane of the larynx below the vocal folds.

The **inferior laryngeal nerves** are the terminal branches that supply motor fibers to all the intrinsic muscles of the larynx except the cricothyroid.

**VARIATIONS.** When the right subclavian artery arises from the descending aorta, the recurrent nerve arises in the neck and passes directly to the larynx.

### *Branches of Vagus Nerve in the Thorax*

**INFERIOR CARDIAC BRANCHES.** The inferior cardiac branches (*thoracic cardiac branches*) arise on the right side from the trunk of the vagus as it lies by the side of the trachea and from the recurrent nerve, and on the left side from the recurrent nerve only. They end in the deep part of the cardiac plexus.

The *visceral efferent fibers to the heart* in all the cardiac branches are preganglionic. After passage through the cardiac and coronary plexuses, these fibers form synapses with groups of ganglion cells in the heart wall, and the postganglionic fibers terminate about the conduction system and musculature of the heart.

The *visceral afferent fibers* from cells in the inferior ganglion traverse the cardiac plexus and cardiac nerves, supplying the heart and great vessels.

The *visceral afferent fibers* that supply the **aortic bodies** (*glomera aortica*) are carried mainly by the cardiac branches of the right vagus, and those that supply the **supracardial bodies** (*aortic paraganglia*) are carried mainly by those of the left vagus. These bodies are chemoreceptors similar to the carotid body; the cell bodies of the afferent fibers are in the inferior ganglion (Hollinshead; 1939, 1940).

**DEPRESSOR NERVE OR NERVE OF CYON.** In some animals, the afferent fibers of the vagus from the heart and great vessels are largely contained in a separate nerve whose stimulation causes depression of the activity of the heart. In man, these fibers are probably contained in the inferior cardiac branches (Mitchell, 1953).

**ANTERIOR BRONCHIAL BRANCHES.** The anterior bronchial branches (*anterior or ventral pulmonary branches*) are two or three small

nerves on the ventral surface of the root of the lung that join with filaments from the sympathetic to form the **anterior pulmonary plexus**. From this plexus, filaments follow the ramifications of the bronchi and pulmonary vessels, or communicate with the cardiac or posterior pulmonary plexuses.

**POSTERIOR BRONCHIAL BRANCHES.** The posterior bronchial branches (posterior or dorsal pulmonary branches) (Fig. 12-25) are numerous offshoots from the main trunk of the vagus as it passes dorsal to the root of the lung. The vagus itself in this region is flat and spread out so that it combines with the bronchial branches and with the sympathetic communications to form what is called the **posterior pulmonary plexus**. The plexus has communications with the cardiac, aortic, and esophageal plexuses and its branches follow the ramifications of the bronchi and pulmonary vessels.

The visceral efferent fibers form synapses with small groups of ganglion cells in the walls of the bronchi, and the postganglionic fibers terminate in the nonstriated muscle and glands of the bronchi.

Afferent fibers supply the lungs and bronchi.

**ESOPHAGEAL BRANCHES.** The esophageal branches (Fig. 12-25) consist of superior filaments from the recurrent nerve and inferior branches from the trunk of the vagus and the esophageal plexus. They contain both visceral efferent (parasympathetic preganglionic) and visceral afferent fibers.

**ESOPHAGEAL PLEXUS.** The fibers of the vagus caudal to the root of the lung split into several bundles (Fig. 12-25), usually two to four larger bundles and a variable number of smaller parallel and communicating strands on each side, which spread out on the esophagus and become partly embedded in its adventitial coat. Filaments are given off for the innervation of the esophagus and there are communications with the splanchnic nerves and sympathetic trunk, forming as a whole the esophageal plexus. The bundles from the left vagus (Fig. 12-24) gradually swing around to the ventral surface of the esophagus; those from the right vagus (Fig. 12-25) swing to the dorsal surface. Just cranial to the diaphragm, the larger bundles from the left vagus usually combine with one or two strands from the right on the ventral surface of the esophagus to form a single

trunk, and this newly constituted vagus, which is not strictly the equivalent of the left vagus, passes through the esophageal hiatus of the diaphragm as the **anterior vagus**. A similar combination on the dorsal surface of the esophagus, mostly right vagus but with a communication from the left, passes through the esophageal hiatus as the **posterior vagus** (Jackson, 1949).

### *Branches of the Anterior and Posterior Vagi in the Abdomen*

The branches in the abdomen (Figs. 12-71; 12-72) contain both visceral efferent (parasympathetic preganglionic) and visceral afferent fibers. The cells of the postganglionic fibers of the stomach and intestines are in the myenteric plexus (of Auerbach<sup>1</sup>) and the submucous plexus (of Meissner<sup>2</sup>); those of the glands are either in small local groups of ganglion cells or possibly in the celiac plexus.

**GASTRIC BRANCHES.** Usually four to six branches are given off by both anterior and posterior vagi at the cardiac end of the stomach. They fan out over their respective surfaces of the fundus and body and penetrate the wall to be distributed to the myenteric and submucous plexuses. On both anterior and posterior surfaces, one branch, longer than the others, follows along the lesser curvature and has been called the *principal nerve of the lesser curvature*; it is distributed to the pyloric vestibule rather than the pylorus itself.

**HEPATIC BRANCHES.** The hepatic branches from the anterior vagus are larger than those from the posterior vagus. They cross from the stomach to the liver in the lesser omentum and continue along the fissure for the ductus venosus to the porta hepatis, where they give off right and left branches to the liver. The large hepatic branch of the anterior vagus contributes to the plexus on the hepatic artery and has the following branches:

(1) Branches to the **gallbladder** and **bile ducts** come from the hepatic branches or the plexus on the artery.

<sup>1</sup>Leopold Auerbach (1828-1897): A German anatomist and neuropathologist (Breslau).

<sup>2</sup>Georg Meissner (1829-1905): A German physiologist (Basle and Göttingen).

(2) A **pancreatic branch** runs dorsalward to its destination.

(3) A branch along the right gastric artery is distributed to the **pylorus** and the first part of the **duodenum**.

(4) A branch accompanies the gastroduodenal artery and right gastroepiploic artery and is distributed to the **duodenum** and **stomach**.

**CELIAC BRANCHES.** A large terminal division of the posterior vagus follows the left gastric artery or runs along the crus of the diaphragm to the celiac plexus. The terminal branches cannot be followed once the nerve has entered the plexus, but the vagus fibers, through the secondary plexuses, reach the duodenum, pancreas, kidney, spleen, small intestine, and large intestine as far as the splenic flexure. Before the nerve enters the plexus it may give a branch to the superior mesenteric artery or to the aortic plexus (see Celiac Plexus).

## XI. THE ACCESSORY NERVE

The **accessory nerve** (eleventh nerve; *spinal accessory nerve*) (Fig. 12-22) is a motor nerve consisting of two parts, a cranial and a spinal part.

**CRANIAL PART.** The cranial part (*r. internus*; accessory portion) arises by four or five delicate **cranial rootlets** from the side of the medulla oblongata, inferior to and in series with those of the vagus. From its deep origin and from its destination, it might well be considered a part of the vagus. It runs lateralward to the jugular foramen, where it interchanges fibers with the spinal part or becomes united with it for a short distance, and has one or two filaments of communication with the superior ganglion of the vagus. It then passes through the jugular foramen, separates from the spinal part and joins the vagus as the **ramus internus**, just proximal to the inferior ganglion. Its fibers are distributed through the pharyngeal branch of the vagus to the uvula, levator veli palatini, and the pharyngeal constrictor muscles, and through the superior and inferior laryngeal branches of the vagus to the muscles of the larynx and the esophagus.

**SPINAL PART.** The spinal part (*r. externus*; *spinal portion*) originates from motor cells in the lateral part of the ventral column of

gray substance of the first five cervical segments of the spinal cord. The fibers pass through the lateral funiculus, emerge on the surface as the **spinal rootlets**, and join each other seriatim as they follow up the cord between the ligamentum denticulatum and the dorsal rootlets of the spinal nerves. The nerve passes through the foramen magnum into the cranial cavity, crosses the occipital bone to the jugular notch, and penetrates the dura mater over the jugular bulb as the **ramus externus** (Fig. 12-1). It passes through the jugular foramen in the same sheath of dura as the vagus, but is separated from it by a fold of the arachnoid. In the jugular foramen, it interchanges fibers with the cranial part or joins it for a short distance and separates from it again. At its exit from the foramen, it turns dorsalward, lying ventral to the internal jugular vein in two-thirds and dorsal to it in one-third of the bodies. It passes posterior to the stylohyoid and digastric muscles to the cranial part of the sternocleidomastoid muscle, which it pierces, and then courses obliquely caudalward across the posterior triangle of the neck to the ventral border of the trapezius muscle (Fig. 12-22). In the posterior triangle it is covered only by the outer investing layer of deep fascia, the subcutaneous fascia and the skin (Fig. 12-35).

**COMMUNICATIONS AND BRANCHES.** The accessory nerve communicates with the second, third, and fourth cervical nerves, and assuming a plexiform arrangement, it continues on the deep surface of the trapezius almost to its caudal border (Fig. 12-22). Experimental observations with monkeys indicate that the communications with the cervical nerves carry proprioceptive sensory fibers from cells in the dorsal root ganglia of the spinal nerves. The branches of the accessory nerve are as follows:

(1) **Sternocleidomastoid branches** are given off as the nerve penetrates this muscle.

(2) **Trapezius branches** are supplied from the part of the nerve lying deep to the muscle.

**VARIATIONS.** The lower limit of the origin of the spinal part may vary from C3 to C7. It may pass beneath the sternocleidomastoid muscle without piercing it, and in one instance it ended in that muscle, the trapezius being supplied by the third and fourth cervical nerves.

## XII. HYPOGLOSSAL NERVE

The **hypoglossal nerve** (twelfth nerve) (Figs. 12-21; 12-36) is the motor nerve of the tongue. Its superficial origin from the medulla oblongata is by a series of rootlets in the ventrolateral sulcus between the pyramid and the olive.

The rootlets are collected into two bundles that perforate the dura mater separately, opposite the hypoglossal canal in the occipital bone, and unite after their passage through it; in some instances the canal is divided by a small bony spicule. As the nerve emerges from the skull, it is deeply placed beneath the internal carotid artery and the internal jugular vein and is closely bound to the vagus nerve. It runs caudalward and forward between the vein and artery, becomes superficial to them near the angle of the mandible, loops around the occipital artery, and passes anteriorly across the external carotid and lingual arteries caudal to the tendon of the digastric muscle (Fig. 12-36). It curves slightly cranialward above the hyoid bone, and passes deep to the tendon of the digastric and the stylohyoid muscle, between the mylohyoid and the hyoglossus muscles, and continues anteriorly among the fibers of the genioglossus as far as the tip of the tongue, distributing branches to the intrinsic muscles.

**COMMUNICATIONS.** The communications with the **vagus nerve** occur close to the skull; numerous filaments pass between the hypoglossal and the inferior ganglion of the vagus through the mass of connective tissue that binds the two nerves together. As the nerve winds around the occipital artery, it communicates by a filament with the **pharyngeal plexus**. The communication with the **sympathetic system** takes place opposite the atlas by branches of the superior cervical ganglion.

The **lingual nerve** communicates with the hypoglossal nerve near the anterior border of the hyoglossus muscle by numerous filaments that lie upon the muscle. The communication that occurs opposite the atlas, between the hypoglossal nerve and the loop connecting the anterior primary divisions of the **first and second cervical nerves** is especially significant because it contains the motor fibers for the nerves to the supra- and infrahyoid muscles. This communication probably also contains sensory fibers

from the cranialmost cervical dorsal root ganglia.

**BRANCHES.** **Meningeal branches** are minute filaments that are given off in the hypoglossal canal and pass back to the dura mater of the posterior cranial fossa. They probably contain sensory fibers communicated to the hypoglossal nerve from the loop between the first and second cervical nerves.

The **superior root of the ansa cervicalis** (descending hypoglossal) (Figs. 12-26; 12-36) is a long slender branch that leaves the hypoglossal nerve as it loops around the occipital artery. It runs along the superficial surface of the carotid sheath to the middle of the neck, gives a branch to the superior belly of the omohyoid muscle, and becomes the medial arm of a loop, the **ansa cervicalis** (*ansa hypoglossi*\*). The lateral arm of the loop is the **inferior root of the ansa cervicalis** (descending cervical) from the second and third cervicals. The branches from the loop supply (1) the inferior belly of the omohyoid, (2) the sternohyoid, and (3) the sternothyroid muscles. The fibers in the descending hypoglossal nerve originate in the first cervical spinal segment, not in the hypoglossal nucleus, and pass through the communication between the first cervical nerve and the hypoglossal nerve described previously.

The **thyrohyoid branch** and the **geniohyoid branch** are also made up of fibers from the first cervical nerve. They leave the hypoglossal nerve near the posterior border of the hyoglossus muscle. The thyrohyoid branch runs obliquely across the greater cornu of the hyoid bone to reach the muscle it supplies.

The **muscular branches** that contain true hypoglossal fibers are distributed to the styloglossus, hyoglossus, genioglossus, and intrinsic muscles of the tongue. At the undersurface of the tongue, numerous slender

\* The Paris Nomenclature has changed the name of this loop from *ansa hypoglossi* to *ansa cervicalis*. The names *ansa hypoglossi*, *descending hypoglossal*, and *descending cervical* are still important to mention because (1) there usually are several cervical loops and (2) the greatest importance of the name, *ansa hypoglossi*, is to the surgeon, who would identify it by its connection with the hypoglossal nerve rather than the cervical nerves. Knowledge of its cervical origin has been obtained largely through clinical observations and animal experimentation, not from dissection.

Fig. 12-26. Plan of hypoglossal and first three cervical nerves.

branches pass cranialward into the substance of the organ to supply its intrinsic muscles. The branches of the hypoglossal nerve to the tongue probably contain proprioceptive sensory fibers with cells of origin in the first (if present) and second cervical dorsal root ganglia.

## Spinal Nerves

The **spinal nerves** arise from the spinal cord within the spinal canal and pass out through the intervertebral foramina. The 31 pairs are grouped as follows: 8 cervical; 12 thoracic; 5 lumbar; 5 sacral; 1 coccygeal. The first cervical leaves the vertebral canal between the occipital bone and the atlas and is therefore called the **suboccipital nerve**; the eighth cervical nerve leaves between the seventh cervical and first thoracic vertebrae.

**ROOTS OF THE SPINAL NERVES.** Each spinal nerve is attached to the spinal cord by two roots, a ventral or motor root, and a dorsal or sensory root (Figs. 11-21; 12-27).

The **ventral root** (anterior root; motor root) emerges from the ventral surface of the spinal cord as a number of rootlets or filaments (*fila radicularia*), which usually combine to form two bundles near the intervertebral foramen.

The **dorsal root** (posterior root; sensory root) is larger than the ventral root because of the greater size and number of its rootlets; these are attached along the ventral lateral furrow of the spinal cord and unite to form two bundles, which enter the spinal ganglion.

The dorsal and ventral roots unite immediately beyond the spinal ganglion to form the spinal nerve, which then emerges through the intervertebral foramen. Both nerve roots receive a covering from the pia

FIG. 12-27. Schema showing structure of a typical spinal nerve.

mater and are loosely invested by the arachnoid, the latter being prolonged as far as the points where the roots pierce the dura mater. The two roots pierce the dura separately, each receiving from this membrane a sheath which becomes continuous with the connective tissue of the epineurium after the roots join to form the spinal nerve.

The **spinal ganglion** (*ganglion spinale*, *dorsal root ganglion*) is a collection of nerve cells on the dorsal root of the spinal nerve. It is oval and proportional in size to the dorsal root on which it is situated; it is bifid medially where it is joined by the two bundles of rootlets. The ganglion is usually placed in the intervertebral foramen, immediately outside the dura mater, but there are exceptions to this rule; the ganglia of the first and second cervical nerves lie on the vertebral arches of the axis and atlas respectively, those of the sacral nerves are inside the vertebral canal, and that of the coccygeal nerve is within the sheath of the dura mater.

**Size and Direction.** In the cervical region, the roots of the first four nerves are small, the last four, large, and the dorsal roots, three times as large as the ventral, a larger proportion than in any other

region; their individual filaments are also larger than in the ventral roots. The first cervical is an exception; its dorsal root is smaller than its ventral root. The roots of the first and second cervical nerves are short and run nearly horizontally to their exits from the vertebral canal. The roots of the third to the eighth nerves run obliquely caudalward, the obliquity and length successively increasing.

In the thoracic region the roots, with the exception of the first, are small, and the dorsal root is only slightly larger than the ventral root. They increase successively in length, and in the more caudal thoracic region they descend in contact with the spinal cord for a distance equal to the height of at least two vertebrae before they emerge from the vertebral canal.

The largest roots with the most numerous individual filaments are found in the lumbar and superior sacral regions. The roots of the coccygeal nerve are the smallest. The roots of the lumbar, sacral, and coccygeal nerves run vertically caudalward, and since the spinal cord ends near the lower border of the first lumbar vertebra, the roots of the successive segments are increasingly long. The name **cauda equina** is given to the resulting collection of nerve roots below the termination of the spinal cord. The largest nerve roots, and consequently the largest spinal nerves, are attached to the cervical and to the lumbar swellings of the spinal cord; these are the nerves largely distributed to the upper and lower limbs.

**GRAY RAMI COMMUNICANTES.** The gray rami communicantes (*postganglionic rami*) contain the postganglionic fibers from the adjacent sympathetic chain ganglia. These fibers are visceral efferents that run in the nerves and their branches toward the periphery, where they supply the smooth muscle in the blood vessel walls, the arrectores pilorum muscles, and the sweat glands. Since there are not as many sympathetic ganglia as there are spinal nerves, some ganglia supply rami to more than one nerve. Although variations are common, a simple plan may be given as follows: The first four cervical nerves receive their rami from the superior cervical ganglion; the fifth and sixth cervical nerves, from the middle ganglion; and the seventh and eighth cervical nerves, from the inferior cervical ganglion. The first ten thoracic nerves receive rami from corresponding ganglia, but the eleventh and twelfth receive rami from a single coalesced ganglion. The lumbar and sacral nerves receive their rami from a variable number of ganglia that correspond only approximately with the nerves.

Each spinal nerve usually receives two or three sympathetic gray rami communicantes. They join the nerve just distal to the union between the dorsal and ventral roots, and in the thoracic and upper lumbar region are regularly medial to the white rami communicantes. The latter are the branches of the spinal nerves that carry preganglionic fibers to the sympathetic chain. The ventral and dorsal primary divisions may each receive a ramus, but if the rami join the ventral division only, some of the fibers course back centrally until they can reach the dorsal division (Dass, 1952).

**WHITE RAMUS COMMUNICANTES.** The white ramus communicans (*preganglionic ramus*) is the branch of the spinal nerve through which the preganglionic fibers from the spinal cord reach the sympathetic chain and are thus the roots of the sympathetic ganglia. They arise from the twelve thoracic and first two lumbar nerves only and usually join the sympathetic chain at or near a ganglion. They leave the ventral primary division of the spinal nerve soon after it has emerged from the intervertebral foramen.

A small **meningeal branch** is given off from each spinal nerve immediately after it emerges from the intervertebral foramen. This branch reenters the vertebral canal

through the foramen, supplies afferent fibers to the vertebrae and their ligaments, and carries sympathetic postganglionic fibers to the blood vessels of the spinal cord and its membranes.

**PRIMARY DIVISIONS.** The spinal nerve splits into its two primary divisions, ventral and dorsal, almost as soon as the two roots join, and both divisions receive fibers from both roots.

#### DORSAL PRIMARY DIVISIONS OF THE SPINAL NERVES

The **dorsal primary divisions** are smaller, as a rule, than the ventral divisions. As they arise from the spinal nerve, they are directed dorsalward, and with the exception of those of the first cervical, the fourth and fifth sacral, and the coccygeal, divide into **medial** and **lateral branches** for the supply of the muscles and skin of the dorsal part of the neck and trunk (Fig. 12-52).

#### Cervical Nerves

In the **first cervical** or **suboccipital nerve** the dorsal primary division is larger than the ventral. It emerges from the spinal canal superior to the posterior arch of the atlas and inferior to the vertebral artery to enter the suboccipital triangle. It supplies the muscles that bound this triangle, namely, the rectus capitis posterior major and the obliquus superior and inferior, and it gives branches to the rectus capitis posterior minor and the semispinalis capitis (Fig. 12-28). A filament from the branch to the obliquus inferior joins the dorsal division of the second cervical nerve.

**VARIATIONS.** The first nerve occasionally has a cutaneous branch that accompanies the occipital artery to the scalp and communicates with the greater and lesser occipital nerves.

The dorsal division of the **second cervical nerve** is much larger than the ventral division and is the greatest of the cervical dorsal divisions. It emerges between the posterior arch of the atlas and the lamina of the axis, caudal to the obliquus inferior muscle, which it supplies. It communicates with the first cervical and then divides into a large medial branch and a small lateral branch.

Fig. 12-28. Dorsal primary divisions of the upper three cervical nerves.

The **greater occipital nerve** (Figs. 12-28; 12-35) is the name given to the medial branch because of its size and distribution. It crosses obliquely between the obliquus inferior and the semispinalis capitis muscles, pierces the latter and the trapezius near their attachments to the occipital bone, and becomes subcutaneous (Fig. 12-28). It communicates with the third cervical nerve, runs upward on the back of the head with the occipital artery, and divides into branches that supply the scalp over the vertex and top of the head, communicating with the lesser occipital nerve. It gives muscular branches to the semispinalis capitis.

The **lesser occipital nerve** is described with the ventral primary divisions.

The **lateral branch** (external branch) supplies branches to the splenius and semispinalis capitis muscles and often communicates with the lateral branch of the third nerve.

The dorsal division of the **third cervical nerve** is intermediate in size between the second and fourth. Its medial branch runs between the semispinalis capitis and cervicis muscles, pierces the splenius and the trapezius, and gives branches to the skin.

The **third occipital nerve** (least occipital

nerve) is the cutaneous part of the third nerve. It pierces the trapezius medial to the greater occipital nerve, with which it communicates, and is distributed to the skin of the lower part of the back of the head (Fig. 12-28). The lateral branch communicates with that of the second cervical nerve, supplies the same muscles, and gives a branch to the longissimus capitis muscle.

The dorsal primary divisions of the **fourth to eighth cervical nerves** divide into medial and lateral branches. The medial branches of the fourth and fifth cervical nerves run between the semispinalis capitis and cervicis, which they supply; near the spinous processes of the vertebrae they pierce the splenius and trapezius muscles to end in the skin (Fig. 12-31). Those of the lower three nerves are small and end in the semispinalis cervicis and capitis, the multifidus, and the interspinales. The lateral branches of the lower five nerves supply the splenius, iliocostalis cervicis, and the longissimus capitis and cervicis muscles.

**VARIATIONS.** The dorsal division of the first cervical nerve and the medial branches of the dorsal divisions of the second and third cervical nerves are sometimes joined by the communicating loops to

form a **posterior cervical plexus** (of Cruveilhier).<sup>1</sup> The greater and lesser occipital nerves vary reciprocally with each other; the greater may communicate with the great auricular or posterior auricular nerves, and a branch to the auricula has been observed. The cutaneous branch of the fifth nerve may be lacking and the lower cervical nerves occasionally have cutaneous twigs.

### *Thoracic Nerves*

The dorsal primary divisions of all the thoracic nerves have medial and lateral branches, but the cutaneous branches in the more cranial thorax are different from those in the more caudal thorax.

The **medial branch** (*internal branch*) (Fig. 12-52) from the dorsal divisions of the **upper six thoracic nerves** passes between and supplies the semispinalis and multifidus muscles, pierces the rhomboidei and trapezius, and approaching the surface close to the spinous process of the vertebra (Fig. 12-31), extends out laterally to the skin over the back. The medial branches of the lower six nerves end in the transversospinales and longissimus muscles, usually without cutaneous branches.

The **lateral branches** (*external branches*) run through or deep to the longissimus to the interval between it and the iliocostalis muscles, which they supply. They gradually increase in size from the first to the twelfth; the cranial six nerves end in the muscles, but the more caudal six have **cutaneous branches** that pierce the serratus posterior inferior and the latissimus dorsi along the junction between the fleshy and aponeurotic portions of the latter muscle (Fig. 12-31).

The cutaneous portions of both medial and lateral branches have a caudalward course that becomes more pronounced caudally, so that the twelfth nerve reaches down to the skin of the buttocks. The cutaneous part of the first thoracic nerve may be lacking. Both medial and lateral branches of some nerves may have cutaneous fibers, especially those of the sixth, seventh, and eighth thoracic nerves (Fig. 12-32).

### *Lumbar Nerves*

The medial branches of the dorsal primary divisions of the lumbar nerves run close to the articular processes of the vertebrae and end in the multifidus muscle.

The **lateral branches** supply the sacrospinalis muscle. The upper three give off cutaneous nerves that pierce the aponeurosis of the latissimus dorsi at the lateral border of the sacrospinalis and cross the posterior part of the iliac crest to be distributed, as the **superior clunial nerves**, to the skin of the buttocks as far as the greater trochanter (Fig. 12-31).

### *Sacral and Coccygeal Nerves*

The dorsal divisions of the sacral nerves are small and diminish in size distally; they emerge, except the last, through the posterior sacral foramina under cover of the multifidus muscle.

The **medial branches** of the first three are small and end in the multifidus.

The **lateral branches** of the first three nerves join with one another and with the last lumbar and fourth sacral nerves to form loops on the dorsal surface of the sacrum (Fig. 12-33). From these loops branches run to the dorsal surface of the sacrotuberous ligament and form a second series of loops under the gluteus maximus. From this second series two or three cutaneous branches pierce the gluteus maximus along a line from the posterior superior iliac spine to the tip of the coccyx, and they supply the skin over the medial part of the buttocks.

The dorsal divisions of the last two sacral nerves and the coccygeal nerves do not divide into medial and lateral branches, but unite with each other on the back of the sacrum, to form loops that supply the skin over the coccyx.

### **VENTRAL PRIMARY DIVISIONS OF THE SPINAL NERVES**

The **ventral primary divisions** of the spinal nerves supply the ventral and lateral parts of the trunk and all parts of the limbs. They are, for the most part, larger than the dorsal divisions. In the thoracic region they remain independent of one another, but in the cervical, lumbar, and sacral regions they unite near their origins to form plexuses.

### *Cervical Nerves*

The ventral division of the **first cervical** or **suboccipital nerve** issues from the vertebral canal cranial to the posterior arch of the

<sup>1</sup>Jean Cruveilhier (1791-1874): A French pathologist (Paris).

FIG. 12-29. Distribution of cutaneous nerves. Ventral aspect.

**FIG. 12-30.** Distribution of cutaneous nerves. Dorsal aspect.

**Fig. 12-29, 12-30.** These figures (and others like them) show areas of distribution on the skin supplied by each of the spinal nerves. The work of Sherrington has demonstrated that the "sensory root field" of a particular dorsal root ganglion overlaps that of the zones or "dermatomes" supplied by the ganglion above and below (Fig. 12-32). In fact, fibers carrying different modalities, i.e., pain and touch, vary in the amount of this overlap.

**Fig. 12-31.** Diagram of the distribution of the cutaneous branches of the dorsal divisions of the spinal nerves.

atlas and runs rostralward around the lateral aspect of the superior articular process, medial to the vertebral artery. In most instances it is medial and anterior to the rectus capitis lateralis, but occasionally it pierces the muscle.

The ventral divisions of the other **cervical nerves** pass outward between the anterior and posterior intertransversarii, lying on the grooved cranial surfaces of the transverse processes of the vertebrae. The first four cer-

**Fig. 12-32.** Areas of distribution of the cutaneous branches of the dorsal divisions of the spinal nerves. The areas of the medial branches are in black; those of the lateral, in red. (H. M. Johnston.)

vical nerves form the cervical plexus; the last four, together with the first thoracic, form the brachial plexus. They all receive gray rami communicantes from the sympathetic chain.

### **Cervical Plexus**

The **cervical plexus** (Fig. 12-34) is formed by the ventral primary divisions of the first four cervical nerves; each nerve, except the first, divides into a superior and inferior branch, and the branches unite to form three loops. The sympathetic rami may join the nerves or the loops. The plexus is situated opposite the cranial four cervical vertebrae.

FIG. 12-33. The dorsal divisions of the sacral nerves.

ventrolateral to the levator scapulae and scalenus medius and deep to the sternocleidomastoid muscle.

The cervical plexus has communications with certain cranial nerves and muscular and cutaneous branches, which may be arranged in tabular form as follows; the numbers indicate the segmental components.

#### A. Communications of the Cervical Plexus

- |                           |           |
|---------------------------|-----------|
| 1. With vagus nerve       | C 1, 2    |
| 2. With hypoglossal nerve | C 1, 2    |
| 3. With accessory nerve   | C 2, 3, 4 |

#### B. Superficial or Cutaneous Branches

- |                        |        |
|------------------------|--------|
| 1. Lesser occipital    | C 2    |
| 2. Great auricular     | C 2, 3 |
| 3. Anterior cutaneous* | C 2, 3 |
| 4. Supraclavicular     | C 3, 4 |

#### C. Deep or Muscular Branches

- |  |           |
|--|-----------|
| 5. Rectus capitis anterior and lateralis | C 1, 2    |
| 6. Longus capitis and colli              | C 1, 2, 3 |
|  | C 2, 3, 4 |

- |                         |           |
|-------------------------|-----------|
| 7. Geniohyoid           | C 1, (2)  |
| Thyrohyoid              | C 1, (2)  |
| Omohyoid (superior)     | C 1, (2)  |
| 8. Sternohyoid          | C 2, 3    |
| Sternothyroid           | C 2, 3    |
| Omohyoid (inferior)     | C 2, 3    |
| 9. Phrenic              | C 3, 4, 5 |
| 10. Sternocleidomastoid | C 2, 3    |
| 11. Trapezius           | C 3, 4    |
| 12. Levator scapulae    | C 3, 4    |
| 13. Scalenus medius     | C 3, 4    |

\*This name conforms with names in more caudal segments.

#### COMMUNICATIONS OF THE CERVICAL PLEXUS

**VAGUS NERVE.** The communication with the vagus nerve is between the loop connecting the first and second nerves and the inferior ganglion.

**HYPOGLOSSAL NERVE.** The communication with the hypoglossal nerve (Figs. 12-26; 12-34) is a short bundle that leaves the loop between the first and second nerves. The great bulk of its fibers are from the first nerve; it runs distally with hypoglossal nerve for 3 or 4 cm and leaves it again as the superior root (descending hypoglossal). It contains motor

FIG. 12-34. Plan of the cervical plexus.

and proprioceptive fibers for certain hyoid muscles and is described later as part of the ansa cervicalis (*ansa hypoglossi*).

**ACCESSORY NERVE.** The communications with the accessory nerve (Fig. 12-34) leave the cervical plexus at several points: (a) one leaves the loop between the second and third nerves, frequently appearing to come from the lesser occipital nerve (C 2), and joins the fibers of the accessory, which supply the sternocleidomastoid; (b) a bundle leaves the third nerve, sometimes in association with the great auricular nerve, and joins the accessory fibers to the trapezius; (c) one or two bundles leave the fourth nerve and join the accessory nerve directly or enter into a network on the deep surface of the trapezius. These communications contain proprioceptive sensory fibers (Corbin and Harrison, 1939).

#### SUPERFICIAL OR CUTANEOUS BRANCHES OF THE CERVICAL PLEXUS

**LESSER OCCIPITAL NERVE.** The lesser occipital nerve (Fig. 12-35) arises from the second cervical nerve or the loop between the second and third nerves and ascends along the sternocleidomastoid muscle, curving around its posterior border. Near the insertion of the muscle on the cranium, it perforates the deep fascia and continues upward along the side of the head behind the ear, supplying the skin and communicating with the greater occipital nerve, the great auricular nerve, and the posterior auricular branch of the facial nerve. It has an auricular branch that supplies the upper and back part of the auricle, communicating with the mastoid branch of the great auricular nerve.

Fig. 12-35. The nerves of the scalp, face, and side of neck.

**VARIATIONS.** The lesser occipital nerve varies reciprocally with the greater occipital nerve; it is frequently duplicated or may be wanting.

**GREAT AURICULAR NERVE.** The great auricular nerve (Fig. 12-35), larger than the preceding, arises from the second and third nerves, winds around the posterior border of the sternocleidomastoid muscle, and after perforating the deep fascia, ascends on the surface of that muscle but deep to the platysma and divides into an anterior and a posterior branch.

The **anterior branch** (facial branch) is distributed to the skin of the face over the parotid gland. It communicates in the substance of the gland with the facial nerve.

The **posterior branch** (mastoid branch) supplies the skin over the mastoid process and back of the auricle except its upper part; a filament pierces the auricle to reach its lateral surface, where it is distributed to the lobule and lower part of the concha. It communicates with the smaller occipital nerve, the auricular branch of the vagus, and the posterior auricular branch of the facial nerve.

**ANTERIOR CUTANEOUS NERVE.** The anterior cutaneous nerve (Fig. 12-35) arises from the second and third cervical nerves and bends around the posterior border of the sternocleidomastoid at its middle. Crossing the surface of the muscle obliquely as it runs horizontally ventralward, it perforates the

deep fascia, passing deep to the external jugular vein, pierces the platysma, and divides into ascending and descending branches.

The **ascending branches** (*rr. superiores*) pass cranialward to the submandibular region, pierce the platysma, and are distributed to the cranial, ventral, and lateral parts of the neck. One filament accompanies the external jugular vein toward the angle of the mandible and communicates with the cervical branch of the facial nerve under cover of the platysma.

The **descending branches** (*rr. inferiores*) pierce the platysma and are distributed to the skin of the ventral and lateral parts of the neck as far down as the sternum.

**SUPRACLAVICULAR NERVES.** The supraclavicular nerves (*descending branches*) (Fig. 12-35) arise from the third and fourth (mainly the fourth) cervical nerves. They emerge from under the posterior border of the sternocleidomastoid muscle and cross the posterior triangle of the neck under cover of the investing layer of deep fascia. Near the clavicle they perforate the fascia and platysma in three bundles or groups—medial, intermediate and lateral.

The **medial supraclavicular nerves** (*anterior supraclavicular nerves*; *suprasternal nerves*) cross the external jugular vein, the clavicular head of the sternocleidomastoid muscle, and the clavicle to supply the skin of the medial infraclavicular region as far as the midline. They furnish one or two filaments to the sternoclavicular joint.

The **intermediate supraclavicular nerves** (*middle supraclavicular nerves*) cross the clavicle and supply the skin over the pectoralis major and the deltoid and they communicate with the cutaneous branches of the more cranial intercostal nerves.

The **lateral supraclavicular nerves** (*posterior supraclavicular nerves*; *supracromial nerves*) pass obliquely across the outer surface of the trapezius and the acromion, and supply the skin of the cranial and dorsal parts of the shoulder.

**VARIATIONS.** One of the middle supraclavicular nerves may perforate the clavicle.

#### DEEP OR MUSCULAR BRANCHES OF THE CERVICAL PLEXUS

**RECTUS CAPITIS BRANCHES.** Branches to the rectus capitis anterior and rectus capitis

lateralis come from the loop between the first and second nerves.

**LONGUS CAPITIS AND COLLI BRANCHES.** Branches to the longus capitis and longus colli are given off separately; for the capitis from the first, second, and third; for the colli from the second, third, and fourth nerves.

**HYOID MUSCULATURE BRANCHES.** Branches to the hyoid musculature (Fig. 12-36) are described previously as branches of the hypoglossal nerve, but the fibers do not come from the hypoglossal nucleus in the brain; they originate instead from the cervical segments of the spinal cord. Fibers communicated to the hypoglossal nerve from the first cervical nerve or from the loop between the first and second nerves leave the hypoglossal nerve again to appear as (1) individual branches to the **geniohyoid**, **thyrohyoid** or **superior belly** of the **omohyoid**, or (2) as the **superior root** (*descendens hypoglossi*) to join the **inferior root** (*descendens cervicalis*) from the second and third cervical nerves to form the **ansa cervicalis** (*ansa hypoglossi*).

The nerve to the **geniohyoid** leaves the hypoglossal nerve distally and has a course similar to that of the thyrohyoid nerve.

The nerve to the **thyrohyoid** (Fig. 12-36) leaves the hypoglossal nerve near the posterior border of the hyoglossus and runs obliquely across the greater cornu of the hyoid bone and enters the muscle as a slender filament. It leaves the hypoglossal distal to the origin of the root superior of the ansa.

The fibers for the **superior belly** of the **omohyoid** leave the superior root before it forms the ansa and reach the muscle as a slender filament.

**ANSA CERVICALIS.** The ansa cervicalis (*ansa hypoglossi*) is a loop of slender nerves that may be somewhat plexiform, ventral and lateral to the common carotid artery and internal jugular vein. It is formed by fibers from the first cervical spinal segment that leave the hypoglossal nerve as the **superior root** (*descendens hypoglossi*), and the **inferior root** (*descendens cervicalis*) from the second and third cervical nerves. It usually lies superficial to the carotid sheath at about the level of the cricoid cartilage.

The nerves to the **sternohyoid** and **sternothyroid** muscles leave the convexity of the loop and run down the superficial surface of the carotid artery to enter the muscles at the root of the neck. They may be separate fila-

FIG. 12-36. Hypoglossal nerve, cervical plexus, and their branches.

ments or combined into a single nerve for a variable distance.

The nerve to the **inferior belly** of the **omohyoid** leaves the convexity of the loop and runs lateralward across the neck deep to the intermediate tendon of the muscle to reach the inferior belly.

**VARIATIONS.** The ansa is quite variable in position; it may occur at various levels. Frequently it is high near the bifurcation of the carotid, in which circumstance it may be within the carotid sheath. The superior root may appear to arise wholly or in part from the vagus. A branch to the sternocleidomastoid and filaments entering the thorax to join the vagus or sympathetic have been described.

**PHRENIC NERVE.** The **phrenic nerve** (internal respiratory nerve of Bell<sup>1</sup>) (Fig. 12-37) is generally known as the motor nerve to the

<sup>1</sup>Sir Charles Bell (1774-1842): A Scottish physiologist who worked in London.

diaphragm, but it contains about half as many sensory as motor fibers, and it should not be forgotten that the lower thoracic nerves also contribute to the innervation of the diaphragm. The phrenic nerve originates chiefly from the fourth cervical nerve but is augmented by fibers from the third and fifth nerves. It lies on the ventral surface of the scalenus anterior, gradually crossing from its lateral to its medial border (Fig. 12-36). Under cover of the sternocleidomastoid, it is crossed by the inferior belly of the omohyoid and the transverse cervical and suprascapular vessels. It continues with the scalenus anterior between the subclavian vein and artery, and as it enters the thorax, it crosses the origin of the internal thoracic artery and is joined by the pericardiophrenic branch of this artery. It passes caudalward over the cupula of the pleura and ventral to the root of the lung, then along the lateral aspect of

FIG. 12-37. The phrenic nerve and its relations with the vagus nerve.

the pericardium, between it and the mediastinal pleura, until it reaches the diaphragm, where it divides into its terminal branches. At the root of the neck it is joined by a communication from the sympathetic trunk.

The right nerve is more deeply placed, is shorter, and runs more vertically caudalward than the left. In the upper part of the thorax it is lateral to the right brachiocephalic vein and the superior vena cava (Figs. 12-37; 12-78).

The left nerve is longer than the right because of the inclination of the heart toward the left and because of the more caudal position of the diaphragm on this side. At the

root of the neck it is crossed by the thoracic duct, and in the superior mediastinum it lies between the left common carotid and the subclavian arteries, and is lateral to the vagus as it crosses the left side of the arch of the aorta (Figs. 12-37; 12-79).

The **pleural branches** of the phrenic nerve are very fine filaments supplied to the costal and mediastinal pleura over the apex of the lung.

The **pericardial branches** are delicate filaments to the upper part of the pericardium.

The **terminal branches** pass through the diaphragm separately, and diverging from each other, are distributed on the abdominal

surface to supply the diaphragm muscle and sensory fibers to the peritoneum. On the right side, a branch near the inferior vena cava communicates with the phrenic plexus, which accompanies the inferior phrenic artery from the celiac plexus, and where they join there is usually a small **phrenic ganglion**. On the left, there is a communication with the phrenic plexus also, but without a ganglion.

The **accessory phrenic nerve** is described later.

**VARIATIONS.** The phrenic nerve may receive fibers from the inferior root of the ansa cervicalis, or from the second or sixth nerves. At the root of the neck or in the thorax it may be joined by an accessory phrenic from the fifth nerve or from the nerve to the subclavius. It may arise from the nerve to the subclavius or give a branch to that muscle. It may pass ventral to the subclavian vein or perforate it.

**OTHER BRANCHES.** The branches to the **sternocleidomastoid** may be independent or partly communicate with the accessory

nerve. They are proprioceptive sensory rather than motor nerves and are derived from the second and third nerves (Corbin and Harrison, 1938).

The branches to the **trapezius** are like those to the sternocleidomastoid and are derived from the third and fourth nerves.

Muscular branches to the **levator scapulae** are supplied by the third and fourth nerves.

Branches to the **scalenus medius** are from the third and fourth nerves.

### Brachial Plexus

The **brachial plexus** (Figs. 12-38; 12-39), as its name implies, supplies the nerves to the upper limb. It is formed by the ventral primary divisions of the fifth to eighth cervical nerves and the first thoracic nerves. A communicating loop from the fourth to the fifth cervical nerve and one from the second to the first thoracic nerve also usually contribute to the plexus. It lies in the lateral part of the neck in the clavicular region, extending from the scalenus anterior to the axilla.

FIG. 12-38. Plan of brachial plexus.

## COMPONENTS

The brachial plexus is composed of roots, trunks, divisions, cords, and terminal nerves. The **roots** of the brachial plexus are provided by the anterior primary divisions of the last four cervical nerves and the first thoracic nerve. The trunks are formed from these roots and are named according to their position relative to each other. The **superior trunk** is formed by the union of the fifth and sixth cervical nerves as they emerge between the scalenus medius and anterior. The **middle trunk** is formed by the seventh cervical nerve alone. The **inferior trunk** is formed by the union of the eighth cervical and first thoracic nerves.

The trunks, after a short course, split into **anterior** and **posterior divisions**. The anterior and posterior divisions of the superior and middle trunks are about equal in size, but the posterior division of the inferior trunk is much smaller than the anterior division because it receives a very small or no contribution from the first thoracic nerve. The **cords**, formed from these divisions, are named according to their relation to the axillary artery: **lateral**, **medial**, and **posterior**. The anterior divisions of the superior and middle trunks are united into the lateral cord. The anterior division of the inferior trunk becomes the medial cord. The posterior divisions of all three trunks are united into the posterior cord. The cords in turn break up into the nerves, which are the terminal branches.

## SYMPATHETIC CONTRIBUTIONS TO THE BRACHIAL PLEXUS

The ventral primary divisions of the spinal nerves that enter into the brachial plexus obtain their sympathetic fibers in the form of the gray rami communicantes from the sympathetic chain. The fifth and sixth nerves receive fibers from the middle cervical ganglion; the sixth, seventh, and eighth nerves, from the inferior cervical or stellate ganglion; the first and second thoracic nerves, from the stellate or the first and second thoracic ganglia.

**RELATIONS.** In the neck, the brachial plexus lies in the posterior triangle, being covered by the skin, platysma, and deep fascia; it is crossed by the supraclavicular nerves, the inferior belly of the omohyoid, the external jugular vein, and the transverse cervical artery. The roots emerge between the scaleni ante-

rior and medius, cranial to the third part of the subclavian artery, while the trunk formed by the union of the eighth cervical and first thoracic nerves is placed dorsal to the artery. The plexus next passes dorsal to the clavicle, the subclavius, and the transverse scapular vessels, and lies upon the first digitation of the serratus anterior and the subscapularis. In the axilla it is placed lateral to the first portion of the axillary artery; it surrounds the second part of the artery, one cord lying medial to it, one lateral to it, and one dorsal to it. In the axilla it gives off its terminal branches to the upper limb.

**VARIATIONS.** Variations of the brachial plexus are of several types: (a) variations in the contributions of the spinal nerves to the roots of the plexus, (b) variations in the formation of the trunks, divisions, or cords, (c) variations in the origin or combination of the branches, (d) variations in the relation to the artery.

(a) The fourth cervical nerve contributes to two-thirds of the plexuses, and T 2 contributes to more than one-third. When the contribution from C 4 is large and that from T 2 lacking, the plexus appears to have a more cranial position and has been termed **prefixed**. Similarly, when the contribution from T 2 is large and from C 4 lacking, the plexus appears to have a more caudal position and has been termed **postfixed**. It is doubtful whether this shifting of position is more common than one in which the plexus is spread out to include both C 4 and T 2, or contracted to exclude both. Variations in the contribution to the plexus may be correlated with the position of the limb bud at the time the nerves first grow into it in the embryo (Miller and Detwiler, 1936), and many variations are similar to the usual conditions found in the different primates.

(b) The trunks vary little in their formation from the cervical roots, but the superior and inferior trunks especially may appear to be absent because the nerves split into dorsal and ventral divisions before they combine into trunks. The cords in these instances are formed from the divisions of the nerves but the sources of the fibers can be readily traced and made to correspond with the usual pattern. Many of these instances may be the result of too vigorous a removal of the connective tissue sheaths of the nerves in dissection. The medial cord may receive a contribution from the middle trunk and the lateral cord may receive fibers from C 8 or the lower trunk.

(c) The median nerve may have small heads, either medial or lateral, in addition to the usual two. It appears to receive fibers from all segments entering the plexus in most instances. Many peculiarities involve combined origins of the median and musculocutaneous nerves, with separation into definitive nerves or branches farther down the arm; thus the musculocutaneous nerve gives a branch to the median in the arm in a fourth of the bodies, but a branch from the median to the ulnar is much less frequent. The musculocutaneous nerve frequently receives fibers from C 4 in addition to the usual C 5 and C 6, and appears to receive fibers from C 7 in

only two-thirds. The nerve to the coracobrachialis muscle is a branch of the lateral cord or some part of the plexus (exclusive of C 8 and T 1) other than the musculocutaneous nerve in almost half of the bodies. The ulnar nerve may have a lateral head from the lateral cord, the lateral head of the median, or from C 7; in two-thirds of the plexuses the ulnar nerve may receive fibers from C 7 or possibly more cranial segments. The radial and axillary nerves may be formed from the trunks and divisions without the presence of a true posterior cord. The radial nerve appears to receive fibers from all segments contributing to the plexus in most instances, but participation of C 4 and T 1 is probably incidental because C 4 may not enter the plexus and in a few instances T 1 can be definitely excluded. The axillary nerve probably receives no fibers from C 8 and T 1 and the contribution from C 7 is undetermined.

(d) Among the variations in the relationship between the axillary artery and the brachial plexus, the most common is an artery superficial to the median nerve; also, the median nerve may be split by a branch of the artery. An aberrant axillary artery, i.e., one not derived from the seventh segmental artery, has a different relation to the roots of the plexus depending on whether it was derived from a segmental artery cranial or caudal to the seventh. The cords of the plexus may be split by arterial branches, and communicating loops of nerves may be formed around the artery or its branches.

## BRANCHES OF THE BRACHIAL PLEXUS

The ventral primary divisions of the fifth to eighth cervical nerves give branches before they enter into the plexus, and the brachial plexus may be divided into the branches that arise from the roots, from the trunks, or from the cords and pass into the terminal nerves. From their topographic relation to the clavicle, the branches may be divided into supra- and infraclavicular branches.

### Branches from the Cervical Nerves

Branches of the anterior primary divisions of the last four cervical and first thoracic nerves **before** they enter the **brachial plexus** include:

1. The fifth cervical nerve may contribute to the **phrenic nerve** at its origin.
2. **Muscular branches** from each of the four lower cervical nerves are supplied to the **longus colli** and the **scalenus anterior, medius, and posterior**.

3. The **accessory phrenic nerve** (Fig. 12-37) is an inconstant branch that may come from the nerve to the subclavius or from the fifth nerve. It passes ventral to the subclavian vein and joins the phrenic nerve at the root of the neck or in the thorax, forming a loop around the vein.

**SURGICAL CONSIDERATIONS.** Resection of the phrenic nerve for immobilization of the diaphragm may be only partially successful if the accessory is not resected also. In avulsion of the phrenic nerve, the subclavian vein is in danger of being torn by the loop between the accessory and the phrenic nerves.

### Branches from the Roots (Supraclavicular Branches)

**DORSAL SCAPULAR NERVES.** The dorsal scapular nerve (nerve to the *rhomboides*; posterior scapular nerve) (Fig. 12-38) arises from the fifth cervical nerve near the intervertebral foramen, frequently in common with a root of the long thoracic nerve. It pierces the scalenus medius and runs dorsally as well as caudalward on the deep surface of the levator scapulae to the vertebral border of the scapula. It supplies the rhomboides major and minor, and along with the third and fourth nerves, gives a branch to the levator scapulae muscle.

**LONG THORACIC NERVE.** The long thoracic nerve (external respiratory nerve of Bell; posterior thoracic nerve) (Fig. 12-39) is the

**Fig. 12-39.** The right brachial plexus (infraclavicular portion) in the axillary fossa; viewed from below and in front. The pectoralis major and minor muscles have been largely removed; their attachments have been reflected. (Spalteholz.)

**Fig. 12-40.** Suprascapular and axillary nerves of right side, seen from behind. (Testut.)

nerve to the serratus anterior muscle. It arises by three roots: from the fifth, sixth, and seventh cervical nerves. Those from the fifth and sixth join just after they pierce the scalenus medius; the seventh joins them at the level of the first rib. The nerve runs caudward dorsal to the brachial plexus and axillary vessels and continues along the lateral surfaces of the serratus anterior, under cover of the subscapularis muscle. It sends branches to all the digitations of the serratus; the fibers from the fifth nerve supply the upper part, the sixth the middle, and the seventh the lower part of the muscle.

**VARIATIONS.** The root from the fifth nerve may remain independent; the root from the seventh may be lacking.

#### Branches from the Trunks (Supraclavicular)

**NERVE TO SUBCLAVIUS MUSCLE.** The nerve to the subclavius is a small branch that arises from the superior trunk, although its fibers are mainly from the fifth nerve, and passes ventral to the distal part of the plexus, the subclavian artery, and the subclavian vein to reach the subclavius muscle (Fig. 12-37).

**VARIATIONS.** The accessory phrenic nerve may arise from the subclavius nerve, or the phrenic nerve may supply the branch to the subclavius muscle.

**SUPRASCAPULAR NERVE.** The suprascapular nerve (Fig. 12-40) arises from the superior trunk and takes a more or less direct course across the posterior triangle to the scapular notch, passing dorsal to the inferior belly of the omohyoid muscle and the anterior border of the trapezius. It passes through the notch, under the superior transverse ligament, runs deep to the supraspinatus muscle and around the lateral border of the spine of the scapula into the infraspinous fossa. In the supraspinous fossa it gives a branch to the supraspinatus and an articular filament to the shoulder joint. In the infraspinous fossa, it gives two branches to the infraspinatus and filaments to the shoulder joint and scapula.

#### Branches from the Cords (Infraclavicular Branches)

The infraclavicular branches arise from the three cords of the brachial plexus, but it should be emphasized that a particular

branch of any cord need not contain fibers from all the cervical nerves contributing to that cord. For example, the axillary nerve, from the posterior cord, contains fibers from C 5 and 6 only, not from C 5, 6, 7, 8, and T 1. Likewise, a branch from one of the larger terminal nerves may not contain fibers from all the cervical segments contributing to that nerve; the branch of the radial nerve to the supinator muscle, for example, contains only fibers from C 6.

**PECTORAL NERVES.** The pectoral nerves (Fig. 12-46) are two nerves, one lateral and one medial to the axillary artery, that arise at the level of the clavicle and supply the pectoral muscles.

The **lateral (superior) pectoral nerve** is so named because it is lateral to the artery and arises from the lateral cord of the brachial plexus or from the anterior divisions of the superior and middle trunks just before they unite into the cord. It passes superficial to the first part of the axillary artery and vein, sends a communicating branch to the inferior pectoral branch, and then pierces the clavipectoral fascia to reach the deep surface of the clavicular and cranial sternocostal portions of the pectoralis major muscle.

The **medial (inferior) pectoral nerve** is so named because its origin is from the medial cord of the brachial plexus, medial to the artery. Its origin is more lateral in position with respect to the midline of the body than that of the superior branch. It passes between the axillary artery and vein, gives a branch that joins the communication from the superior branch to form a plexiform loop around the artery, and enters the deep surface of the pectoralis minor muscle. It supplies this muscle and two or three of its branches continue through the muscle to supply the more caudal part of the pectoralis major. The most distal branch may pass around the border of the minor. The loop gives off branches that supply both muscles.

**SUBSCAPULAR NERVES.** The subscapular nerves (Fig. 12-39), usually two in number, arise from the posterior cord of the brachial plexus, deep in the axilla.

The **superior subscapular nerve** (short subscapular), the smaller of the two, enters the superior part of the subscapularis muscle; it is frequently double.

The **inferior subscapular nerve** supplies the distal part of the subscapularis and ends in the teres major muscle.

**VARIATIONS.** The nerve to the teres major may be a separate branch of the posterior cord, or rarely, of the axillary nerve.

**THORACODORSAL NERVES.** The thoracodorsal nerve (middle or long subscapular nerve) (Fig. 12-39) is a branch of the posterior cord of the brachial plexus; it usually arises between the two subscapular nerves. It follows the course of the subscapular and thoracodorsal arteries along the posterior wall of the axilla, under cover of the ventral border of the latissimus dorsi, and terminates in branches that supply this muscle.

**AXILLARY NERVE.** The axillary nerve (circumflex nerve) (Fig. 12-40) is the last branch of the posterior cord of the brachial plexus before the latter becomes the radial nerve. It passes over the insertion of the subscapularis muscle dorsal to the axillary artery, crosses the teres minor, and leaves the axilla, accompanied by the posterior humeral circumflex artery, by passing through the quadrilateral space bounded by the surgical neck of the humerus, the teres major, the teres minor, and the long head of the triceps. It divides into two branches.

The **posterior branch** (lower branch) supplies the teres minor and the posterior part of the deltoid. It then pierces the deep fascia at the posterior border of the deltoid as the **lateral brachial cutaneous nerve**, to supply the skin over the distal two-thirds of the posterior part of this muscle and over the adjacent long head of the triceps brachii.

The **anterior branch** (upper branch) winds around the surgical neck of the humerus with the posterior humeral circumflex vessels, under cover of the deltoid as far as its anterior border. It supplies this muscle and sends a few small cutaneous filaments to the skin covering its distal part.

**Articular filaments** leave the nerve near its origin and in the quadrilateral space; these supply the anterior inferior part of the capsule of the shoulder joint.

**MEDIAL BRACHIAL CUTANEOUS NERVE.** The medial brachial cutaneous nerve (nerve of Wrisberg), a small nerve, arises from the medial cord of the brachial plexus and is distributed to the medial side of the arm. It passes through the axilla, at first lying dorsal and then medial to the axillary vein and brachial artery. It pierces the deep fascia in the middle of the arm and is distributed to the skin of the arm as far as the medial epi-

condyle and olecranon. A part of it forms a loop with the intercostobrachial nerve in the axilla, and there is a reciprocal relationship in size between these two nerves. It also communicates with the ulnar branch of the medial antebrachial cutaneous nerve or it may be a branch of the latter nerve.

**MEDIAL ANTEBRACHIAL CUTANEOUS NERVE.** The medial antebrachial cutaneous nerve (Figs. 12-41 to 12-44; 12-46) arises from the medial cord of the brachial plexus, medial to

FIG. 12-41. Cutaneous nerves of right upper limb. Anterior view.

**FIG. 12-42.** Diagram of segmental distribution of the cutaneous nerves of the right upper limb. Anterior view.

the axillary artery. Near the axilla, it gives off a filament that pierces the fascia and supplies the skin over the biceps nearly as far as the elbow. The nerve runs down the ulnar side of the arm medial to the brachial artery, pierces the deep fascia with the basilic vein about the middle of the arm, and divides into an anterior and an ulnar branch.

The **ulnar branch** (posterior branch) passes obliquely distalward on the medial

**FIG. 12-43.** Cutaneous nerves of right upper limb. Posterior view.

side of the basilic vein, anterior to the medial epicondyle of the humerus to the dorsum of the forearm, and continues on its ulnar side as far as the wrist, supplying the skin. It communicates with the medial brachial cutaneous, the dorsal antebrachial cutaneous, and the dorsal branch of the ulnar nerve.

The **anterior branch** is larger and passes, usually superficial but occasionally deep, to

FIG. 12-44. Diagram of segmental distribution of the cutaneous nerves of the right upper limb. Posterior view.

the median basilic vein. It continues on the anterior part of the ulnar side of the forearm, distributing filaments to the skin as far as the wrist, and communicating with the palmar cutaneous branch of the ulnar nerve.

#### Terminal Branches

The terminal branches of the brachial plexus are the musculocutaneous, median, ulnar, and radial nerves.

**MUSCULOCUTANEOUS NERVE.** The musculocutaneous nerve (Fig. 12-46) is formed by the splitting of the lateral cord of the brachial plexus at the inferior border of the pectoralis minor into two branches, the other branch being the lateral root of the median nerve. It pierces the coracobrachialis muscle, and lying between the brachialis and the biceps brachii, crosses to the lateral side of the arm. A short distance above the elbow it pierces the deep fascia lateral to the tendon of the biceps and continues into the forearm as the lateral antebrachial cutaneous nerve.

The branch to the **coracobrachialis** leaves the nerve close to its origin.

Muscular branches are supplied to the **biceps** and the greater part of the **brachialis**.

An articular filament given off from the nerve to the brachialis supplies the **elbow joint**.

A filament to the **humerus** enters the nutrient foramen with the artery.

The **lateral antebrachial cutaneous nerve** (Figs. 12-41 to 12-44) passes deep to the cephalic vein and divides opposite the elbow joint into an anterior and a dorsal branch.

The **anterior branch** (volar branch) follows along the radial border of the forearm to the wrist and supplies the skin over the radial half of its anterior surface. At the wrist it is superficial to the radial artery, and some of its filaments pierce the deep fascia to follow the vessel to the dorsal surface of the carpus. It terminates in cutaneous filaments at the thenar eminence after communicating with the superficial branch of the radial and the palmar cutaneous branch of the median nerve.

The **dorsal branch** (posterior branch) passes distally along the dorsal part of the radial surface of the forearm, supplying the skin almost to the wrist, and communicating with the dorsal antebrachial cutaneous nerve and the superficial branch of the radial nerve.

**Variations.** The musculocutaneous and median nerves present frequent irregularities in their origins from the lateral cord of the plexus. The branch to the coracobrachialis muscle may be a separate nerve. In this condition the musculocutaneous nerve may continue with the median for a variable distance before it passes under the biceps. Some of the fibers of the median nerve may run for some distance in the musculocutaneous nerve before they join their proper trunk; less frequently the reverse is the case and fibers of the musculocutaneous nerve run with

**Fig. 12-45.** Dermatome chart of the upper limb of man outlined by the pattern of hyposensitivity from loss of function of a single nerve root. (From Keegan and Garrett, *Anat. Rec.*, 102:415, 1948.)

the median. The musculocutaneous nerve may give a branch to the pronator teres or it may supply the dorsum of the thumb in the absence of the superficial branch of the radial nerve.

**MEDIAN NERVE.** The median nerve (Fig. 12-46) is the nerve to the radial side of the flexor portion of the forearm and hand. It takes its origin from the brachial plexus by two large roots, one from the lateral and one from the medial cord. The roots at first lie on each side of the third part of the axillary artery, then embracing it, they unite on its ventral surface to form the trunk of the nerve. In its course down the arm it accompanies the brachial artery, to which it is at first lateral, but gradually it crosses the ventral surface of the artery in the middle or distal part of the arm and lies medial to it at the bend of the elbow, where it is deep to the bicipital fascia and superficial to the brachialis muscle.

In the forearm, the median nerve passes between the two heads of the pronator teres, being separated from the ulnar artery by the deep head. It continues distally between the

flexores digitorum superficialis and profundus almost to the flexor retinaculum, where it becomes more superficial and lies between the tendons of the flexor digitorum superficialis and the flexor carpi radialis. It is deep to the tendon of the palmaris longus and slightly ulnarward of it, and it is the most superficial of the structures that pass through the tunnel under the flexor retinaculum.

In the palm of the hand, the median nerve is covered only by the skin and the palmar aponeurosis and rests on the tendons of the flexor muscles (Fig. 12-47). Immediately after emerging from under the retinaculum, it becomes enlarged and flattened and splits into muscular and digital branches.

**Branches.** The median nerve has no branches above the elbow joint unless, as occasionally happens, the nerve to the pronator teres arises there.

Articular branches to the elbow joint are one or two twigs given off as the nerve passes the joint.

Muscular branches leave the nerve near the elbow and supply all the superficial mus-

FIG. 12-46. Nerves of the left upper limb.

FIG. 12-47. Superficial dissection of the palm of the hand. (Redrawn from Töndury.)

cles of the anterior part of the forearm except the flexor carpi ulnaris, i.e., the **pronator teres**, **flexor carpi radialis**, **palmaris longus**, and **flexor digitorum superficialis**.

The **anterior interosseous nerve** (Fig. 12-46) accompanies the anterior interosseous artery along the anterior surface of the interosseous membrane in the interval between the flexor pollicis longus and the flexor digi-

torum profundus, ending in the pronator quadratus and the wrist joint. It supplies all the deep anterior muscles of the forearm except the ulnar half of the profundus, i.e., the radial half of the flexor digitorum profundus, the flexor pollicis longus, and the pronator quadratus.

The **palmar branch of the median nerve** (Fig. 12-42) pierces the antebrachial fascia

distal to the wrist and divides into a medial and a lateral branch. The medial branch supplies the skin of the palm and communicates with the palmar cutaneous branch of the ulnar nerve. The lateral branch supplies the skin over the thenar eminence and communicates with the lateral antebrachial cutaneous nerve.

The **muscular branch in the hand** (Fig. 12-48) is a short stout nerve that leaves the radial side of the median nerve, sometimes in company with the first common palmar digi-

tal nerve, just after the former passes under the flexor retinaculum. It supplies the muscles of the thenar eminence with the exception of the deep head of the short flexor, i.e., the abductor pollicis brevis, the opponens pollicis and the superficial head of the flexor pollicis brevis.

The **first common palmar digital nerve** (Figs. 12-48; 12-50) divides into three proper palmar digital nerves (*digital collaterals*), two of which supply the sides of the thumb; the third gives a twig to the first lumbrical

**FIG. 12-48.** Dissection of the palm of the hand, showing the superficial palmar arch, median and ulnar nerves, and synovial sheaths. (Redrawn from Töndury.)

and continues as the proper palmar digital nerve for the radial side of the index finger.

The **second common palmar digital nerve** gives a twig to the second lumbrical, and continuing to the web between the index and middle fingers, splits into proper digital nerves for the adjacent sides of these fingers.

The **third common palmar digital nerve** occasionally gives a twig to the third lumbrical, in which case it has a double innervation; it communicates with a branch of the ulnar nerve, and continues to the web between the middle and the ring fingers, where it splits into proper digital nerves for the adjacent sides of these digits.

The **proper digital nerves** (*digital collaterals*) (Figs. 12-47; 12-48; 12-50) supply the skin of the palmar surface and the dorsal surface over the terminal phalanx of their digits. At the end of the digit each nerve terminates in two branches, one of which ramifies in the skin of the ball, the other in the pulp under the nail. They communicate with the dorsal digital branches of the superficial radial nerve, and in the fingers they are superficial to the corresponding arteries.

**Variations.** In 16 per cent of bodies studied, the relation of the median nerve to the two heads of the pronator teres varies from that described; it may pass deep to the humeral head in the absence of an ulnar head, or deep to the ulnar head, or split the humeral head (Jamieson and Anson, 1952). There is overlapping of territory in the innervation of the flexor digitorum profundus by the median and ulnar nerves in 50 per cent of bodies; it is twice as common for the median to encroach on the ulnar. The portion of the profundus attached to the index finger is the only part of that muscle constantly supplied by one nerve, the median. In the majority of cases the profundus and the lumbrical of a particular digit are innervated by the same nerve. Encroachment of the median on the ulnar is less common for the lumbricals than the profundus. The median nerve may supply the first dorsal interosseus (Sunderland 1945, 1946).

**ULNAR NERVE.** The ulnar nerve (Fig. 12-46) occupies a superficial position along the medial side of the arm and is the nerve to the muscles and skin of the ulnar side of the forearm and hand. It is the terminal continuation of the medial cord of the brachial plexus, after the medial head of the median nerve has separated from it. It is medial, at first to the axillary artery and then to the brachial artery as far as the middle of the

arm, and is parallel with and not far distant from the median and medial antebrachial cutaneous nerves. In the middle of the arm it angles dorsally, pierces the medial intermuscular septum, and follows along the medial head of the triceps muscle to the groove between the olecranon and the medial epicondyle of the humerus. In this position it is covered only by the skin and fascia and can readily be palpated as the "funny bone" of the elbow.

The ulnar nerve is accompanied in its course through the distal half of the arm by the superior ulnar collateral artery and the ulnar collateral branch of the radial nerve. It enters the forearm between the two heads of the flexor carpi ulnaris and continues between this muscle and the flexor digitorum profundus half way down the forearm. In the proximal part of the forearm it is separated from the ulnar artery by a considerable distance, but in the distal half it lies close to its ulnar side, radialward from the flexor carpi ulnaris, and covered only by the skin and fascia. Proximal to the wrist it gives off a large dorsal branch and continues into the hand, where it has muscular and digital branches.

**Branches.** The ulnar nerve usually has no branches proximal to the elbow. Distal to the elbow its branches are as follows:

The articular branches to the **elbow joint** are several small filaments that leave the nerve as it lies in the groove between the olecranon and the medial epicondyle of the humerus.

Two muscular branches arise near the elbow and supply the **flexor carpi ulnaris** and the ulnar half of the **flexor digitorum profundus**.

The **palmar cutaneous branch** of the ulnar nerve arises near the middle of the forearm and accompanies the ulnar artery into the hand. It gives filaments to the artery, perforates the flexor retinaculum, and ends in the skin of the palm, communicating with the palmar branch of the median nerve.

The **dorsal branch** (Figs. 12-43; 12-46) arises in the distal half of the forearm and reaches the dorsum of the wrist by passing between the flexor carpi ulnaris and the ulna. It pierces the deep fascia and divides into two **dorsal digital nerves** and a metacarpal communicating branch. The more medial digital nerve supplies the ulnar side of the little finger; the other digital branch, the

adjacent sides of the little and ring fingers. The metacarpal branch supplies the skin of that area and continues toward the web between the ring and middle fingers, where it joins a similar branch of the superficial radial nerve to supply the adjacent sides of these two fingers. On the little finger the dorsal digital branches extend only as far as the base of the terminal phalanx, and on the ring finger as far as the base of the second phalanx; the more distal parts of these digits are supplied by the dorsal branches of the proper palmar digital nerves from the ulnar nerve.

The **palmar branch** or terminal portion of the ulnar nerve crosses the ulnar border of the wrist in company with the ulnar artery, superficial to the flexor retinaculum and under cover of the palmaris brevis, and divides into a superficial and deep branch.

The **superficial branch** (Figs. 12-48; 12-50) supplies the palmaris brevis and the skin of

the hypothenar eminence and divides into **digital branches**. A **proper palmar digital branch** goes to the ulnar side of the little finger; a **common palmar digital branch** divides into proper digital branches for the adjacent sides of the little and ring fingers and communicates with the branches of the median nerve. The proper digital branches are distributed to the fingers in the same manner as those of the median nerve.

The **deep branch** (Figs. 12-49; 12-50) passes between the abductor digiti minimi and flexor digiti minimi brevis accompanied by the deep branch of the ulnar artery; it then pierces the opponens digiti minimi and follows the course of the deep palmar arch across the interossei, deep to the midpalmar and thenar fascial clefts. Near its origin it gives branches to the three small muscles of the little finger, and as it crosses the hand it supplies the third and fourth lumbricals and all the interossei, both palmar and dor-

**FIG. 12-49.** Deep dissection of the palm of the hand, showing the deep palmar arch and the deep palmar branch of the ulnar nerve. (Redrawn from Töndury.)

FIG. 12-50. Deep palmar nerves. (Testut.)

sal. It ends by supplying the adductores pollicis and the deep head of the flexor pollicis brevis. It also sends articular filaments to the wrist joint.

**Variations.** The ulnar nerve may pass in front of the medial epicondyle. It frequently has a communication with the median nerve in the forearm and rarely with the medial antebrachial cutaneous, median, or musculocutaneous nerves in the arm. It may send muscular branches to the medial head of the triceps, the flexor digitorum superficialis, the first and second lumbricals and the superficial head of the flexor pollicis brevis muscles. It may have defi-

ciencies on the dorsum of the hand that are supplied by the radial nerve or it may encroach upon the area usually supplied by that nerve. See variations of the median nerve and brachial plexus.

**RADIAL NERVE.** The radial nerve (musculo-spiral nerve) (Fig. 12-51), the largest branch of the brachial plexus, is the continuation of the posterior cord; it supplies the extensor muscles of the arm and forearm as well as the skin covering them. It crosses the tendon of the latissimus dorsi, deep to the axillary artery, and after passing the inferior border

**FIG. 12-51.** The suprascapular, axillary, and radial nerves.

of the teres major, it winds around the medial side of the humerus and enters the substance of the triceps between the medial and long heads. It takes a spiral course down the arm close to the humerus in the groove that separates the origins of the medial and lateral heads of the triceps, accompanied by the deep brachial artery. Having reached the lateral side of the arm, it pierces the lateral intermuscular septum and runs between the

brachialis and the brachioradialis anterior to the lateral epicondyle, where it divides into superficial and deep branches (Fig. 12-46).

**Branches in the Arm.** Both muscular and cutaneous branches of the radial nerve are found in the arm.

The **medial muscular branches** arise in the axilla and supply the medial and long heads of the triceps. The branch to the medial head is a long filament that accompanies the ulnar nerve and superior ulnar collateral artery as far as the lower third of the arm and is therefore named the **ulnar collateral nerve**.

The **posterior brachial cutaneous nerve** (*internal cutaneous branch of the musculospiral*) arises in the axilla to the medial side of the arm, supplying the skin on the dorsal surface nearly as far as the olecranon. In its course it crosses dorsal to, and communicates with, the intercostobrachial nerve.

The **posterior muscular branches** arise from the nerve as it lies in the spiral groove of the humerus; they supply the medial and lateral heads of the triceps and the anconeus. The nerve to the latter muscle is a long, slender filament that lies buried in the substance of the medial head of the triceps.

The **posterior antebrachial cutaneous nerve** (*external cutaneous branch of the musculospiral*) perforates the lateral head of the triceps at its attachment to the humerus and divides into proximal and distal branches. The smaller **proximal branch** lies close to the cephalic vein and supplies the skin of the dorsal part of the distal half of the arm. The **distal branch** pierces the deep fascia below the insertion of the deltoid and continues along the lateral side of the arm and elbow and the dorsal side of the forearm to the wrist. It supplies the skin in its course, and near its termination, it communicates with the dorsal branch of the lateral antebrachial cutaneous nerve.

The **lateral muscular branches** supply the brachioradialis, the extensor carpi radialis longus, and the lateral part of the brachialis.

**Articular branches** to the elbow come from the radial nerve between the brachialis and brachioradialis, from the ulnar collateral nerve, and from the nerve to the anconeus.

**Branches in the Forearm.** The **superficial branch of the radial nerve** (Fig. 12-46) runs along the lateral border of the forearm under cover of the brachioradialis muscle. In the proximal third of the forearm it gradually

approaches the radial artery; in the middle third it lies just radialward to the artery; and in the lower third it quits the artery and angles dorsally under the tendon of the brachioradialis toward the dorsum of the wrist, where it pierces the deep fascia and divides into two branches.

The **lateral branch** is smaller, supplies the skin of the radial side and ball of the thumb, and communicates with the palmar branch of the lateral antebrachial cutaneous nerve.

The **medial branch** communicates above the wrist, with the dorsal branch of the lateral antebrachial cutaneous nerve, and on the dorsum of the hand, with the dorsal branch of the ulnar nerve. It then divides into four **dorsal digital nerves** (Fig. 12-43), which are distributed as follows: (1) to the ulnar side of the thumb, (2) to the radial side of the index finger, (3) to the adjacent sides of the index and middle fingers, and (4) to the dorsal branch of the ulnar nerve to form a communication, and to the adjacent sides of the middle and ring fingers.

The **deep branch of the radial nerve** (posterior interosseous nerve) (Fig. 12-51) winds to the dorsum of the forearm around the radial side of the radius between the planes of fibers of the supinator muscle and continues between the superficial and deep layers of muscles to the middle of the forearm. Considerably diminished in size, and named the **dorsal interosseous nerve**, it lies on the dorsal surface of the interosseous membrane, and under cover of the extensor pollicis longus, it continues to the dorsum of the carpus, where it ends.

**Muscular branches** of the deep branch of the radial nerve to the extensor carpi radialis brevis and the supinator are given off before the nerve turns dorsally. After passing through the supinator, branches are given to the extensor digitorum, extensor digiti minimi, extensor carpi ulnaris, the two extensores and abductor longus pollicis, and the extensor indicis.

**Articular filaments** from a terminal plexus of the radial nerve are distributed to the ligaments and articulations of the carpus and metacarpus.

**VARIATIONS.** The radial nerve may pass through the quadrilateral space with the axillary nerve, and when the profunda brachii supplies the nutrient artery of the humerus, it may be accompanied by a filament from the radial. The nerve to the brachialis

muscles is inconstant. The deep branch may pass superficial to the entire supinator. There is great variation in the distribution and overlapping of the radial and ulnar nerves on the back of the hand; the most frequent arrangement appears to be that the radial supplies three and a half digits, the ulnar, one and a half digits (Sunderland, 1945, 1946).

### Thoracic Nerves

The ventral primary divisions (anterior divisions) (Fig. 12-52) of the thoracic nerves number 12 on each side. The first eleven, situated between the ribs, are termed **intercostals**; the twelfth lies below the last rib and is called the **subcostal nerve**. The intercostal nerves are distributed chiefly to the parietes of the thorax and abdomen, and they differ from the other spinal nerves in that each pursues an independent course, i.e., they do not enter into a plexus. The first two contribute to the upper limb as well as to the thorax; the next four are limited in their distribution to the thorax; the lower five supply the parietes of the thorax and the abdomen. The twelfth thoracic nerve is distributed to the abdominal wall and the skin of the buttock.

### RAMI COMMUNICANTES

Each thoracic nerve contributes preganglionic sympathetic fibers to the sympathetic chain through a **white ramus communicans**, and receives postganglionic fibers from the chain ganglia through **gray rami communicantes**. Both rami are attached to the spinal nerves near their exit from the intervertebral foramina, the gray rami being more medial than the white. For more details see the section on the Sympathetic System.

### FIRST THORACIC NERVE

The ventral primary division of the first thoracic nerve divides immediately into two parts: (1) the larger part leaves the thorax ventral to the neck of the first rib and becomes one of the roots of the brachial plexus (described previously); (2) the smaller part becomes the **first intercostal nerve**. The first intercostal nerve runs along the first intercostal space to the sternum, perforates the muscles and deep fascia, and ends as the first anterior cutaneous nerve of the thorax. It has no lateral cutaneous branch, as a rule, but it may have a communication with the intercostobrachial branch of the second

FIG. 12-52. Plan of a typical intercostal nerve.

nerve. A communication between the first and second nerves inside the thorax occurs frequently and contains postganglionic sympathetic fibers from the second or even the third thoracic sympathetic ganglion.

#### SUPERIOR THORACIC NERVES

The ventral primary divisions of the second to the sixth thoracic nerves and the intercostal portion of the first thoracic are known as the **thoracic intercostal nerves** (Figs. 12-53; 12-54; 12-78). They pass ventralward in the intercostal spaces with the intercostal vessels; from the vertebral column to the angles of the ribs, they lie between the pleura and the posterior intercostal mem-

brane; from the angle to the middle of the ribs, they pass between the intercostales interni and externi. They then enter the substance of the intercostales interni, where they remain concealed until they reach the costal cartilages; here they again emerge on the inner surface of the muscle and lie between it and the pleura. The nerves are inferior to the vessels and, like them, are at first close to the rib above, but as they proceed ventrally they may approach the middle of the intercostal space. Near the sternum they pass ventral to the transversus thoracis and the internal thoracic vessels, and near the sternum they pierce the intercostalis internus, the anterior intercostal membrane, the pectoralis major and the pec-

FIG. 12-53. Cutaneous distribution of thoracic nerves. (Testut.)

toral fascia, terminating as the **anterior cutaneous nerves** of the thorax. They have short medial and longer lateral branches that supply the skin and mamma.

**MUSCULAR BRANCHES.** Muscular branches supply the intercostales interni and externi, the subcostales, the levatores costarum, the

serratus posterior superior, and the transversus thoracis. At the ventral part of the thorax some of these branches cross the costal cartilages from one intercostal space to another.

**CUTANEOUS BRANCHES.** The **lateral cutaneous nerves** (Figs. 12-53; 12-54) arise from the intercostal nerves about midway be-

Fig. 12-54. Intercostal nerves, the superficial muscles having been removed. (Testut.)

tween the vertebral column and the sternum, pierce the intercostales externi and serratus anterior, and divide into anterior and posterior branches. The anterior branches supply the skin of the lateral and ventral part of the chest and mammae; those of the fifth and sixth nerves also supply the cranial digitations of the obliquus externus abdominis. The posterior branches supply the skin over the latissimus dorsi and the scapular region.

The **intercostobrachial nerve** (Figs. 12-39; 12-41; 12-46) arises from the second intercostal nerve as if it were a lateral cutaneous nerve, but it fails to divide into an anterior and a posterior branch. After piercing the intercostales and the serratus anterior, it crosses the axilla, embedded in the adipose tissue, to reach the medial side of the arm. It forms a loop of communication with the medial brachial cutaneous nerve of the brachial plexus and assists it in supplying

the skin of the medial and posterior part of the arm. It also communicates with the posterior brachial cutaneous branch of the radial nerve.

An intercostobrachial branch frequently arises from the third intercostal nerve, supplying the axilla and medial side of the arm.

### LOWER THORACIC NERVES

The ventral primary divisions of the seventh to eleventh thoracic nerves are continued beyond the intercostal spaces into the anterior abdominal wall and are named the **thoracoabdominal intercostal nerves** (Figs. 12-53; 12-54). They have the same arrangement as the upper nerves as far as the anterior ends of the intercostal spaces, where they pass dorsal to the costal cartilages. They run ventralward between the obliquus internus and transversus abdominis muscles, pierce the sheath of the rectus abdominis, which they supply, and terminate as the **anterior cutaneous branches**.

**MUSCULAR BRANCHES.** Muscular branches supply the intercostales, the obliqui, and transversus abdominis muscles; the last three also supply the serratus posterior inferior.

**CUTANEOUS BRANCHES.** The **lateral cutaneous branches** (Figs. 12-53; 12-54) arise midway along the nerves, pierce the intercostales externi and the obliquus externus in line with the lateral cutaneous branches of the upper intercostals, and divide into anterior and posterior branches. The anterior branches give branches to the digitations of the obliquus externus and extend caudalward and ventralward nearly as far as the margin of the rectus abdominis, supplying the skin. The posterior branches pass dorsally to supply the skin over the latissimus dorsi.

The **anterior cutaneous branches** penetrate the anterior layer of the sheath of the rectus abdominis and divide into medial and lateral branches that supply the skin of the anterior part of the abdominal wall.

### TWELFTH THORACIC NERVE

The anterior primary division of the **twelfth thoracic** (Figs. 12-53; 12-54; 12-57) or **subcostal nerve** is larger than those above it. It runs along the inferior border of the twelfth rib, often communicates with the first lumbar nerve, and passes under the lateral lumbocostal arch. It crosses the ventral

surface of the quadratus lumborum, penetrates the transversus abdominis, and continues ventralward to be distributed in the same manner as the lower intercostal nerves. It communicates with the iliohypogastric nerve of the lumbar plexus and gives a branch to the pyramidalis. The lateral cutaneous branch is large and does not divide into anterior and posterior branches. It perforates the obliqui muscles, passes downward over the crest of the ilium ventral to a similar branch of the iliohypogastric nerve, and is distributed to the skin of the anterior part of the gluteal region, some filaments extending as far down as the greater trochanter.

### Lumbar Nerves and Lumbosacral Plexus

The ventral primary divisions are increasingly large as they are placed more caudally in the lumbar region. Their course is lateralward and caudalward, either under cover of the psoas major muscle or between its fasciculi. The first three nerves and the larger part of the fourth nerve are connected by communicating loops, and they are frequently joined by a communication from the twelfth thoracic nerve, forming the lumbar plexus. The smaller part of the fourth nerve joins the fifth to form the lumbosacral trunk, which enters the sacral plexus. The fourth nerve, because it is divided between the two plexuses, is sometimes called the **nervus furcalis**.

Only the first two lumbar nerves contribute preganglionic sympathetic fibers to the sympathetic chain through **white rami communicantes**. All the lumbar nerves receive postganglionic fibers from the sympathetic chain through **gray rami communicantes**. For more details see the section on the Sympathetic Nervous System.

**Muscular branches** are supplied to the psoas major and the quadratus lumborum from the ventral primary divisions of the lumbar nerves before they enter the lumbar plexus.

The **lumbosacral plexus** is the name given to the combination of all the ventral primary divisions of the lumbar, sacral, and coccygeal nerves. The lumbar and sacral plexuses supply the lower limb, but in addition the sacral nerves supply the perineum through the pudendal plexus and the coccygeal region through the coccygeal plexus. For convenience in description, these plexuses will be considered separately.

## LUMBAR PLEXUS

The **lumbar plexus** (Fig. 12-55) is formed by the ventral primary divisions of the first three and the greater part of the fourth lumbar nerves, with a communication from the twelfth thoracic usually joining the first lumbar nerve. It is situated on the inside of the posterior abdominal wall, either dorsal to the psoas major or among its fasciculi, and ventral to the transverse processes of the lumbar vertebrae. The lumbar plexus is not an intricate interlacement like the brachial plexus, but its branches usually arise from two or three nerves, so that the resulting junctions between adjacent nerves have the appearance of loops.

The manner in which the plexus is formed is the following (Figs. 12-55; 12-56): the first lumbar nerve, usually supplemented by a communication from the twelfth thoracic nerve, splits into a cranial and a caudal branch. The cranial branch forms the **iliohypogastric** and **ilioinguinal** nerves; the caudal and smaller branches unite with a branch from the second lumbar nerve to form the

**genitofemoral** nerve. The remainder of the second nerve and the third and fourth nerves each split into a small ventral and a large dorsal portion; the ventral portions unite into one nerve, the **obturator**. The dorsal portions of the second and third nerves each divide again into unequal branches; the two smaller branches unite to form the **lateral femoral cutaneous** nerve; the two larger branches join the dorsal portion of the fourth nerve to form the **femoral** nerve. The **accessory obturator** nerve, which is present in about one out of five individuals, comes from the third and fourth nerves. A considerable part of the fourth nerve joins the fifth lumbar nerve in the **lumbosacral trunk**.

The **branches** of the lumbar plexus are as follows:

1. Iliohypogastric	L 1, (T 12)
2. Ilioinguinal	L 1
3. Genitofemoral	L 1, 2
4. Lateral femoral cutaneous	L 2, 3
5. Obturator	L 2, 3, 4
6. Accessory obturator	L 3, 4
7. Femoral	L 2, 3, 4

FIG. 12-55. Plan of lumbar plexus.

Fig. 12-56. The lumbar plexus and its branches.

These branches may be divided into two groups according to their distribution. The first three supply the caudal part of the parietes of the abdominal wall; the last four supply the anterior thigh and medial part of the leg.

**ILIOHYPOGASTRIC NERVE.** The iliohypogastric nerve (Figs. 12-56; 12-58) arises from the first lumbar nerve and from the communication with the twelfth thoracic nerve, when this is present. It emerges from the upper part of the lateral border of the psoas major, crosses the quadratus lumborum to the crest of the ilium, and penetrates the posterior part of the transversus abdominis near the crest of the ilium. Between the transversus and the obliquus internus it divides into a lateral and anterior cutaneous branch.

The **lateral cutaneous branch** (iliac

branch) pierces the obliqui internus and externus immediately above the iliac crest, and is distributed to the skin of the gluteal region posterior to the lateral cutaneous branch of the twelfth thoracic nerve (Figs. 12-57; 12-64); these two nerves are inversely proportional in size.

The **anterior cutaneous branch** (hypogastric branch) (Figs. 12-54; 12-58) continues its course between the obliquus internus and transversus, pierces the former, and becomes subcutaneous by passing through a perforation in the aponeurosis of the obliquus externus about 2 cm above the superficial inguinal ring. It is distributed to the skin of the hypogastric region (Fig. 12-27).

**Muscular branches** are supplied to the obliquus internus and transversus.

**ILIOINGUINAL NERVE.** The ilioinguinal

**FIG. 12-58.** Cutaneous nerves of right lower limb. Anterior view.

**GENITOFEMORAL NERVE.** The genitofemoral nerve (**genitocrural nerve**) (Figs. 12-56; 12-57; 12-59) arises from the first and second lumbar nerves and passes caudalward through the substance of the psoas major until it emerges on its ventral surface opposite the third or fourth lumbar vertebra, where it is covered by transversalis fascia and peritoneum. On the surface of the muscle, or occasionally within its substance, it divides into a genital and a femoral branch.

The **genital branch** (external spermatic nerve) continues along the psoas major to the inguinal ligament, where it either pierces the transversalis and internal spermatic fascia or passes through the internal inguinal ring to reach the spermatic cord. It lies against the dorsal aspect of the cord, supplies the cremaster muscle, and is distributed to the skin of the scrotum and adjacent thigh. In the female it accompanies the round ligament of the uterus.

The **femoral branch** (lumboinguinal nerve) lies on the psoas major, lateral to the genital branch, and passes under the inguinal ligament with the external iliac artery. It enters the femoral sheath, superficial and lateral to the artery, then pierces the sheath and fascia lata to supply the skin of the proximal part of the anterior surface of the thigh. It gives a filament to the femoral artery and communicates with the anterior cutaneous branches of the femoral nerve (Figs. 12-58; 12-59).

**VARIATIONS.** The iliohypogastric or ilioinguinal nerves may arise from a common trunk, or the ilioinguinal nerve may join the iliohypogastric at the iliac crest, with the latter nerve then supplying the missing branches. The ilioinguinal nerve may be lacking and the genital branch supplies its branches, or the genital branch may be absent and the ilioinguinal substitutes for it. The femoral branch and lateral femoral cutaneous nerves or the anterior cutaneous branches of the femoral nerve may substitute for each other to a greater or lesser extent.

**LATERAL FEMORAL CUTANEOUS NERVE.** The **lateral femoral cutaneous nerve** (external cutaneous nerve) (Figs. 12-55; 12-58) arises from the dorsal portion of the ventral primary divisions of the second and third lumbar nerves. It emerges from the lateral border of the psoas major about its middle, and runs across the iliacus muscle obliquely toward the anterior superior iliac spine. It

FIG. 12-59. Diagram of segmental distribution of the cutaneous nerves of the right lower limb. Anterior view.

then passes under the inguinal ligament and over the sartorius muscle into the subcutaneous tissues of the thigh, dividing into an anterior and a posterior branch (Fig. 12-57).

The **anterior branch** becomes superficial about 10 cm distal to the inguinal ligament and is distributed to the skin of the lateral and anterior parts of the thigh as far as the knee (Fig. 12-58). The terminal filaments communicate with the anterior cutaneous branches of the femoral nerve and the infrapatellar branches of the saphenous nerve, forming the **patellar plexus**.

The **posterior branch** pierces the fascia lata and subdivides into filaments that pass posteriorly across the lateral and posterior surfaces of the thigh, supplying the skin from the level of the greater trochanter to the middle of the thigh (Fig. 12-64).

**OBTURATOR NERVE.** The obturator nerve (Figs. 12-55; 12-56), the motor nerve to the adductores muscles, arises by three roots from the ventral portions of the second, third, and fourth lumbar nerves; the root from the third lumbar nerve is the largest, and that from the second is often very small. The obturator emerges from the medial border of psoas major near the brim of the pelvis, under cover of the common iliac vessels, and passes lateral to the hypogastric vessels and the ureter. It runs along the lateral wall of the lesser pelvis to enter the upper part of the obturator foramen with the obturator vessels. As it enters the thigh it divides into anterior and posterior branches, which are separated by some of the fibers of the obturator externus muscle and the adductor brevis muscle.

**Anterior Branch.** The anterior or superficial branch (Fig. 12-60) communicates with the accessory obturator nerve, when this is present, and passes over the superior border of the obturator externus, deep to the pectineus and adductor longus and superficial to the adductor brevis. At the distal border of the adductor longus it communicates with the anterior cutaneous and saphenous branches of the femoral nerve, forming the **subsartorial plexus**, and terminates in filaments accompanying the femoral artery.

An **articular branch** to the hip joint is given off near the obturator foramen. **Muscular branches** are supplied to the adductor longus, gracilis, and usually to the adductor brevis; in rare instances it gives a branch to the pectineus muscle.

**FIG. 12-60.** Nerves of the right lower limb. Anterior view.

A **cutaneous branch** is occasionally found as a continuation of the communication with the anterior cutaneous and saphenous branches. It emerges from beneath the inferior border of the adductor longus and continues along the posterior margin of the sartorius to the medial side of the knee, where it pierces the deep fascia, communicates with the saphenous nerve, and is distributed to the skin of the medial side of the proximal half of the leg.

**Posterior Branch.** The **posterior branch** pierces the anterior part of the obturator externus, passes posterior to the adductor brevis and anterior to the adductor magnus, and divides into muscular and articular branches.

**Muscular branches** are given to the obturator externus as it passes between its fibers, to the adductor magnus, and to the adductor brevis when it is not supplied by the anterior branch.

The **articular branch** for the knee joint either perforates the adductor magnus or passes under the arch through which the femoral artery passes and enters the popliteal fossa. It accompanies the popliteal artery, supplying it with filaments, and reaches the back of the knee joint, where it perforates the oblique popliteal ligament and is distributed to the synovial membrane.

**ACCESSORY OBTURATOR NERVE.** The accessory obturator nerve (Fig. 12-56) is a small nerve present in about 29% of cases. It arises from the ventral part of the third and fourth lumbar nerves, follows along the medial border of the psoas major, and crosses over the superior ramus of the pubis instead of going through the obturator foramen with the obturator nerve. It passes deep to the pectineus muscle, supplying it with branches, communicates with the anterior branch of the obturator nerve, and sends a branch to the hip joint.

**VARIATIONS.** When the obturator nerve has a cutaneous branch, the medial cutaneous branch of the femoral nerve is correspondingly small. When the accessory obturator is lacking, the obturator nerve supplies two nerves to the hip joint; the accessory may be very small and be lost in the capsule of the hip joint.

**FEMORAL NERVE.** The femoral nerve (*anterior crural nerve*) (Figs. 12-55 to 12-60), the largest branch of the lumbar plexus and the

principal nerve of the anterior part of the thigh, arises from the dorsal portions of the ventral primary divisions of the second, third, and fourth lumbar nerves. It emerges through the fibers of the psoas major at the distal part of its lateral border and passes down between it and the iliacus, being covered by the iliac portion of the transversalis fascia. The femoral nerve passes under the inguinal ligament, lateral to the femoral artery, and breaks up into branches soon after it enters the thigh. **Muscular branches** to the iliacus are given off within the abdomen. The **anterior cutaneous branches** are two large nerves: the intermediate and medial cutaneous nerves (Fig. 12-58).

**Intermediate Cutaneous Nerve.** The **intermediate cutaneous nerve** (middle cutaneous nerve) pierces the fascia lata (and generally the sartorius) about 7.5 cm distal to the inguinal ligament. It divides into two branches that descend in immediate proximity along the anterior thigh to supply the skin as far distally as the anterior knee. Here they communicate with the medial cutaneous nerve and the infrapatellar branch of the saphenous, thereby forming the **patellar plexus**. In the proximal part of the thigh the lateral branch of the intermediate cutaneous nerve communicates with the femoral branch of the genitofemoral nerve.

**Medial Cutaneous Nerve.** The **medial cutaneous nerve** (internal cutaneous nerve) passes obliquely across the proximal part of the sheath of the femoral artery, and divides into two branches, an anterior and a posterior, anterior to or at the medial side of that vessel. Before dividing, it gives off a few filaments that accompany the great saphenous vein and pierce the fascia lata to supply the integument of the medial side of the thigh. One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh; a third pierces the fascia at its lower third. The **anterior branch** runs distalward on the sartorius, perforates the fascia lata at the distal third of the thigh, and divides into two branches: one supplies the integument as far distally as the medial side of the knee; the other crosses to the lateral side of the patella, communicating in its course with the infrapatellar branch of the saphenous nerve. The posterior branch descends along the medial border of the sartorius muscle to the knee, where it pierces the fascia lata, communi-

cates with the saphenous nerve, and gives off several cutaneous branches. It then passes down to supply the integument of the medial side of the leg. Beneath the fascia lata, at the lower border of the adductor longus, it forms a plexiform network (**subsartorial plexus**) with branches of the saphenous and obturator nerves.

**Variations.** When the communicating branch from the obturator nerve is large and continues to the integument of the leg, the posterior branch of the medial cutaneous nerve is small and terminates in the plexus, occasionally giving off a few cutaneous filaments.

**Nerve to Pectineus.** The nerve to the pectineus arises immediately below the inguinal ligament, and passes deep to the femoral sheath to enter the anterior surface of the muscle; it is often double.

**Nerve to Sartorius.** The nerve to the sartorius arises in common with the intermediate cutaneous nerve and enters the deep surface of the proximal part of the muscle.

**Saphenous Nerve.** The saphenous nerve (Figs. 12-58; 12-60; 12-64) is the largest and longest branch of the femoral nerve; it supplies the skin of the medial side of the leg. It passes deep to the sartorius in company with the femoral artery, and lies anterior to the artery, crossing from its lateral to its medial side, within the fascial covering of the adductor canal (Fig. 8-61). At the tendinous arch in the adductor magnus, it quits the artery, penetrates the fascial covering of the adductor canal, continues along the medial side of the knee deep to the sartorius, and pierces the fascia lata between the tendons of the sartorius and the gracilis to become subcutaneous. It then accompanies the great saphenous vein along the tibial side of the leg, and at the medial border of the tibia in the distal third of the leg, it divides into two terminal branches.

One branch joins the medial cutaneous and obturator nerves in the middle of the thigh to form the **subsartorial plexus**.

A large **infrapatellar branch**, given off at the medial side of the knee, pierces the sartorius and fascia lata and is distributed to the skin in front of the patella. Above the knee it communicates with the anterior cutaneous branches of the femoral nerve; below the knee it communicates with other branches of the saphenous nerve; and on the lateral

side of the joint, it communicates with branches of the lateral femoral cutaneous nerve to form the **patellar plexus**.

Branches below the knee are distributed to the skin of the anterior and medial side of the leg, communicating with the medial cutaneous nerve and the cutaneous branch of the obturator, if present. One branch continues along the margin of the tibia, and ends at the ankle. The other terminal branch passes anterior to the ankle and is distributed to the medial side of the foot, as far as the ball of the great toe, communicating with the medial branch of the superficial peroneal nerve.

**Branches to the Quadriceps Femoris.** The branch to the rectus femoris enters the proximal part of the deep surface of the muscle (Fig. 12-60). The large branch to the vastus lateralis accompanies the descending branch

of the lateral femoral circumflex artery to the distal part of the muscle. The branch to the vastus medialis muscle runs parallel with the saphenous nerve, lateral to the femoral vessels and outside of the adductor canal, and it enters the muscle near its middle. The two or three branches to the vastus intermedius, enter the anterior surface of the muscle about the middle of the thigh; a filament from one of these descends through the muscle to the articularis genu and the knee joint.

**Articular Branches.** The articular branch to the **hip joint** is derived from the nerve to the rectus femoris.

Articular branches to the **knee joint** are three in number. (1) A long slender filament derived from the nerve to the vastus lateralis penetrates the capsule of the joint on its anterior aspect. (2) A filament derived from the nerve to the vastus medialis can usually be

FIG. 12-61. Dissection of side wall of pelvis showing sacral and pudendal plexuses. (Testut.)

**FIG. 12-62.** Dermatome chart of the lower limb of man outlined by the pattern of hyposensitivity from loss of function of a single nerve root. (From Keegan and Garrett, *Anat. Rec.*, 102:417, 1948.)

traced downward on the surface of this muscle; it pierces the muscle and accompanies the articular branch of the descending genicular artery to the medial side of the articular capsule, which it penetrates, to supply the synovial membrane. (3) The branch to the vastus intermedius, which supplies the articularis genu, also is distributed to the knee joint.

### **Sacral and Coccygeal Nerves and Sacral Plexus**

The ventral primary divisions of the sacral coccygeal nerves enter into the formation of the sacral and pudendal plexuses. Those from the first four sacral nerves enter the pelvis through the anterior sacral foramina; the fifth enters between the sacrum and coccyx, and the coccygeals enter below the first

piece of the coccyx. The first and second sacrals are large; the third, fourth, and fifth diminish progressively in size.

The **sacral plexus** (Figs. 12-61; 12-63; 12-70) is formed by the lumbosacral trunk from the fourth and fifth lumbar nerves and by the first, second, and third sacral nerves. They converge toward the caudal part of the greater sciatic foramen and unite into a large flat band, most of which is continued into the thigh as the sciatic nerve. The plexus lies against the posterior and lateral walls of the pelvis, between the piriformis and the internal iliac vessels, which are embedded in the pelvic subserous fascia. The nerves that enter the plexus, with the exception of the third sacral, split into ventral and dorsal portions, and the branches that arise from them are listed in the chart that appears at the top of page 1236.

FIG. 12-63. Plan of sacral and coccygeal plexuses.

#### NERVE TO QUADRATUS FEMORIS AND GEMELLUS INFERIOR

The nerve to the quadratus femoris and gemellus inferior, from the ventral portions of L 4, 5, and S 1, leaves the pelvis through the greater sciatic foramen, distal to the piriformis and ventral to the sciatic nerve. It runs ventral or deep to the tendon of the obturator internus and gemelli and enters the

deep surface of the quadratus and gemellus inferior.

An articular branch is given to the hip joint.

#### NERVE TO OBTURATOR INTERNUS AND GEMELLUS SUPERIOR

The nerve to the obturator internus and gemellus superior (Fig. 12-66), from the ventral portions of L 5, and S 1, 2, leaves the pel-

## Branches From the Sciatic Plexus

	Ventral Portions	Dorsal Portions
1. Nerve to quadratus femoris and gemellus inferior	L 4, 5, S 1	
2. Nerve to obturator internus and gemellus superior	L 5, S 1, 2	
3. Nerve to piriformis		S (1), 2
4. Superior gluteal		L 4, 5, S 1
5. Inferior gluteal		L 5, S 1, 2
6. Posterior femoral cutaneous	S 2, 3	S 1, 2
7. Perforating cutaneous		S 2, 3
8. Sciatic		
a. Tibial	L 4, 5, S 1, 2, 3	
b. Common peroneal		L 4, 5, S 1, 2
9. (Pudendal)	S 2, 3, 4	

vis through the greater sciatic foramen distal to the piriformis. It gives off the branch to the gemellus superior, then crosses the spine of the ischium, reenters the pelvis through the lesser sciatic foramen, and enters the pelvic surface of the obturator internus.

## NERVE TO PIRIFORMIS

The **nerve to the piriformis**, from the dorsal portions of S 2 or S 1, 2, enters the ventral surface of the muscle; it may be double.

## SUPERIOR GLUTEAL NERVE

The **superior gluteal nerve** (Figs. 12-66; 12-70), from the dorsal portions of L 4, 5, and S 1, leaves the pelvis through the greater sciatic foramen proximal to the piriformis, and accompanying the superior gluteal vessels and their branches, divides into a superior and an inferior branch.

The **superior branch** is distributed to the gluteus minimus muscle. The **inferior branch** crosses the gluteus minimus, gives filaments to the gluteus medius and minimus, and ends in a branch to the tensor fasciae latae.

## INFERIOR GLUTEAL NERVE

The **inferior gluteal nerve**, from the dorsal portions of L 5, and S 1, 2, leaves the pelvis through the greater sciatic foramen distal to the piriformis and enters the deep surface of the gluteus maximus.

## POSTERIOR FEMORAL CUTANEOUS NERVE

The **posterior femoral cutaneous nerve** (small sciatic nerve) (Figs. 12-64 to 12-66) is distributed to the skin of the perineum and the posterior surface of the thigh and leg. It arises from the dorsal portions of S 1 and 2 and from the ventral divisions of S 2 and 3, and leaves the pelvis through the greater sciatic foramen distal to the piriformis. It accompanies the inferior gluteal artery to the inferior border of the gluteus maximus and runs down the posterior thigh, superficial to the long head of the biceps femoris and deep to the fascia lata to the back of the knee. It pierces the deep fascia and accompanies the small saphenous vein to the middle of the back of the leg, its terminal twigs communicating with the sural nerve.

The three or four **inferior clunial branches** (gluteal branches) turn upward around the lower border of the gluteus maximus and supply the skin covering the lower and lateral part of that muscle.

The **perineal branches** (Fig. 12-66) arise at the lower border of the gluteus maximus, run medially over the origin of the hamstrings toward the groove between the thigh and perineum, and pierce the deep fascia to supply the skin of the external genitalia and adjacent proximal medial surface of the thigh. One long branch, the inferior pudendal (long scrotal nerve) (Fig. 12-70), runs ventrally in the fascia of the perineum to the skin of the scrotum and base of the penis in the male or to the skin of the labium majus in the female, communicating with the pos-

**Fig. 12-64.** Cutaneous nerves of right lower limb. Posterior view.

**Fig. 12-65.** Diagram of the segmental distribution of the cutaneous nerves of the right lower limb. Posterior view.

**FIG. 12-66.** Nerves of the right lower limb. Posterior view. (In this diagram the medial and lateral sural cutaneous are not in their normal position. They have been displaced by the removal of the superficial muscles.)

terior scrotal and inferior rectal branches of the pudendal nerve.

The **femoral branches** consist of numerous filaments from both sides of the nerve that are distributed to the skin of the posterior and medial sides of the thigh and the popliteal fossa (Fig. 12-64).

The **sural branches** are usually two terminal twigs that supply the skin of the posterior leg to a varying extent and communicate with the sural nerve.

**VARIATIONS.** When the tibial and peroneal nerves arise separately, the posterior femoral cutaneous nerve also arises from the sacral plexus in two parts. The ventral portion accompanies the tibial nerve and gives off the perineal and medial femoral branches; the dorsal portion passes through the piriformis with the peroneal nerve and supplies the gluteal and lateral femoral branches. The inferior pudendal branch may pierce the sacrotuberous ligament. The sural branches may be lacking or may extend down as far as the ankle.

#### PERFORATING CUTANEOUS NERVE

The **perforating cutaneous nerve** (*n. clunium inferior medialis*) arises from the posterior surface of the second and third sacral nerves. It pierces the caudal part of the sacrotuberous ligament, winds around the inferior border of the gluteus maximus, and is distributed to the skin over the medial and caudal parts of that muscle.

**VARIATIONS.** The perforating cutaneous nerve is lacking in one third of the bodies; its place may be taken by a branch of the posterior femoral cutaneous nerve, or by a branch from S 3 and 4, or S 4 and 5. It may pierce the gluteus maximus as well as the ligament, or instead of piercing the ligament it may accompany the pudendal nerve or go between the muscle and the ligament. It may arise in common with the pudendal nerve.

#### SCIATIC NERVE

The **sciatic nerve** (*n. ischiadicus*; great sciatic nerve) (Fig. 12-66) is the largest nerve in the body. It supplies the skin of the foot and most of the leg, the muscles of the posterior thigh, all the muscles of the leg and foot, and contributes filaments to all the joints of the lower limb. It is the continuation of the main part of the sacral plexus, arising from L 4, 5 and S 1, 2, 3. It passes out of the pelvis through the greater sciatic foramen and extends from the inferior border of the piri-

formis to the distal third of the thigh, where it splits into two large terminal divisions, the **tibial** and **common peroneal nerves**. In the proximal part of its course it rests upon the posterior surface of the ischium, between the ischial tuberosity and the greater trochanter of the femur, and crosses the obturator internus, gemelli, and quadratus femoris. It is accompanied by the posterior femoral cutaneous nerve and the inferior gluteal artery and is covered by the gluteus maximus. More distally it lies upon the adductor magnus and is crossed obliquely by the long head of the biceps femoris.

The tibial and common peroneal nerves represent two divisions within the sciatic nerve that are manifest at the origin of the nerve and preserve their identity throughout its length, although combined into one large nerve by a common connective tissue sheath. The tibial division takes its origin in the sacral plexus from the ventral divisions of L 4, 5, and S 1, 2, 3; the peroneal division originates from the dorsal divisions of L 4, 5 and S 1, 2. In some bodies these two divisions remain separate throughout their course, no true sciatic nerve being formed.

#### Articular Branches

**Articular branches** arise from the proximal part of the nerve and supply the hip joint, perforating the posterior part of the capsule. They may arise from the sacral plexus.

#### Muscular Branches

The **muscular branches** to the hamstrings, viz., the long head of the biceps femoris, the semitendinosus, and the semimembranosus muscles, and to the adductor magnus come from the tibial division; the branch to the short head of the biceps comes from the common peroneal division.

#### Tibial Nerve

The **tibial nerve** (*medial popliteal nerve*) (Fig. 12-66), the larger of the two terminal divisions of the sciatic nerve, is composed of fibers from the ventral portions of L 4, 5 and S 1, 2, 3. It continues in the same direction as the sciatic nerve, at first deep to the long head of the biceps, then through the middle of the popliteal fossa covered by adipose tis-

sue and fascia. After crossing the popliteus muscle, it passes between the heads of the gastrocnemius and under the soleus. It remains deep to these muscles down to the medial margin of the tendo calcaneus, along which it runs to the flexor retinaculum and there divides into the medial and lateral plantar nerves. At its origin it is some distance lateral to the popliteal artery and vein, but as it continues in a straight course it crosses superficial to the vessels in the popliteal fossa, and, lying medial to them, passes with them under the tendinous arch formed by the soleus. It accompanies the posterior tibial artery, at first being medial but soon crossing the artery and lying lateral to it down to the ankle.

**ARTICULAR BRANCHES OF TIBIAL NERVE.** Articular branches supply the knee and ankle joints.

Three branches, accompanying the superior and inferior medial genicular and the middle genicular arteries, pierce the ligaments and supply the **knee joint**. The superior branch is inconstant. Just proximal to the bifurcation at the flexor retinaculum, an articular branch is given off to the **ankle joint**.

**MUSCULAR BRANCHES OF TIBIAL NERVE.** Muscular branches are supplied to the muscles of the posterior leg. Branches that arise as the nerve lies between the two heads of the gastrocnemius are distributed to both heads of the gastrocnemius, plantaris, soleus, and popliteus; the latter branch turns around the distal border and is distributed to the deep surface of the muscle. Arising more distally, either separately or by a common trunk, are branches to the soleus, tibialis posterior, flexor digitorum longus, and flexor hallucis longus; the branch to the last muscle accompanies the peroneal artery; that to the soleus enters the deep surface of the muscle.

**MEDIAL SURAL CUTANEOUS NERVE.** The medial sural cutaneous nerve (*n. communicans tibialis*) remains superficial in the groove between the two heads of the gastrocnemius, accompanied by the small saphenous vein. Near the middle of the back of the leg, it pierces the deep fascia and is joined by the communicating ramus of the lateral sural cutaneous branch of the peroneal nerve to form the sural nerve.

**SURAL NERVE.** The sural nerve (*short saphenous nerve*) (Fig. 12-64) is formed by the union of the medial sural cutaneous nerve

and the communicating ramus of the lateral sural cutaneous nerve (peroneal anastomotic). Lying with the small saphenous vein near the lateral margin of the tendo calcaneus, it continues distally to the interval between the lateral malleolus and the calcaneus, supplying branches to the skin of the back of the leg and communicating with the posterior femoral cutaneous nerve. The nerve turns anteriorly below the lateral malleolus and is continued as the **lateral dorsal cutaneous nerve** along the lateral side of the foot and little toe (Fig. 12-58). It communicates on the dorsum of the foot with the intermediate dorsal cutaneous nerve, a branch of the superficial peroneal nerve.

**MEDIAL CALCANEAL BRANCHES.** The medial calcaneal branches (*internal calcaneal branches*) (Fig. 12-66) perforate the flexor retinaculum and are distributed to the skin of the heel and medial side of the sole of the foot.

**MEDIAL PLANTAR NERVE.** The medial plantar nerve (*internal plantar nerve*) (Fig. 12-67), the larger of the two terminal branches of the tibial nerve, accompanies the medial

plantar artery. From its origin under the flexor retinaculum, it passes deep to the abductor hallucis, and appearing between this muscle and the flexor digitorum brevis, it gives off the proper plantar digital nerve to the great toe. It finally divides opposite the bases of the metatarsal bones into three common digital nerves.

**Branches of the Medial Plantar Nerve.** The plantar cutaneous branches pierce the plantar aponeurosis between the abductor hallucis and the flexor digitorum brevis and are distributed to the skin of the sole of the foot (Fig. 12-68).

**Muscular branches** for the abductor hallucis and flexor digitorum brevis arise from the trunk of the nerve and enter the deep surfaces of the muscles. A branch for the flexor hallucis brevis springs from the proper digital nerve to the medial side of the great toe. A branch for the first lumbrical comes from the first common digital nerve.

The **articular branches** supply the joints of the tarsus and metatarsus.

The **proper digital nerve** of the great toe pierces the plantar aponeurosis posterior to the tarsometatarsal joint, sends a branch to the flexor hallucis brevis, and is distributed to the skin of the medial side of the great toe (Fig. 12-67).

The **three common digital nerves** pass between the divisions of the plantar aponeurosis; each splits into the two **proper digital nerves**. Those of the first common digital supply the adjacent sides of the great and

**FIG. 12-67.** The plantar nerves.

**FIG. 12-68.** Diagram of the segmental distribution of the cutaneous nerves of the sole of the foot.

second toes; those of the second, the adjacent sides of the second and third toes; those of the third, the adjacent sides of the third and fourth toes. The first common digital nerve gives a twig to the first lumbrical. The third communicates with the lateral plantar nerve. Each proper digital nerve gives off cutaneous and articular filaments along the digit, finally terminating in the ball of the toe, and opposite the distal phalanx sends a dorsal branch that is distributed to the structures around the nail.

**LATERAL PLANTAR NERVE.** The lateral plantar nerve (*external plantar nerve*) (Figs. 12-67; 12-68) supplies the skin of the fifth and lateral half of the fourth toes, as well as most of the deep muscles of the foot; its distribution is similar to that of the ulnar nerve in the hand. It passes distally with the lateral plantar artery to the lateral side of the foot, lying between the flexor digitorum brevis and the quadratus plantae, and in the interval between the former muscle and the abductor digiti minimi, it divides into a superficial and a deep branch.

**Branches of the Lateral Plantar Nerve.** Muscular branches to the quadratus plantae and the abductor digiti minimi are given off before the division into superficial and deep branches.

The **superficial branch** splits into a common digital nerve and a nerve that supplies the proper digital for the lateral side of the little toe, and muscular branches to the flexor digiti minimi brevis and the two interossei of the fourth intermetatarsal space. The common digital nerve has a communication with the third common digital branch of the medial plantar nerve and divides into two proper digital nerves that are distributed to the adjacent sides of the fourth and fifth toes.

The **deep branch** accompanies the lateral plantar artery on the deep surface of the tendons of the flexors longi and the adductor hallucis. It supplies all the interossei except those in the fourth intermetatarsal space, the second, third, and fourth lumbricals, and the adductor hallucis.

#### Common Peroneal Nerve

The **common peroneal nerve** (*lateral popliteal nerve; peroneal nerve*) (Fig. 12-66), the smaller of the two terminal divisions of the sciatic nerve, is composed of fibers from the dorsal portions of L 4, 5 and S 1, 2. It runs

obliquely along the lateral side of the popliteal fossa, close to the medial border of the biceps femoris and between that muscle and the lateral head of the gastrocnemius, to the head of the fibula. It winds around the neck of the fibula and passes deep to the peroneus longus, where it divides into the superficial and deep peroneal nerves.

**ARTICULAR BRANCHES.** There are three articular branches to the knee: (a) one accompanies the superior lateral genicular artery to the knee, occasionally arising from the trunk of the sciatic nerve; (b) one accompanies the inferior lateral genicular artery to the joint; and (c) the third (recurrent) articular nerve is given off at the point of division of the common peroneal nerve and accompanies the anterior tibial recurrent artery through the substance of the tibialis anterior to the anterior part of the knee (Fig. 12-60, not labeled).

**LATERAL SURAL CUTANEOUS NERVE.** The **lateral sural cutaneous nerve** (*lateral cutaneous branch*) is distributed to the skin of the posterior and lateral surfaces of the leg (Fig. 12-65) and has an important communicating ramus. The **communicating ramus** (*peroneal anastomotic nerve*) (Figs. 12-64; 12-66) arises near the head of the fibula, crosses superficial to the lateral head of the gastrocnemius, and in the middle of the leg joins the medial sural cutaneous nerve to form the sural nerve.

**DEEP PERONEAL NERVE.** The deep peroneal nerve (*anterior tibial nerve*) (Figs. 12-60; 12-69), arising from the bifurcation of the common peroneal nerve between the fibula and the peroneus longus, continues deep to the extensor digitorum longus to the anterior surface of the interosseous membrane. It meets the anterior tibial artery in the proximal third of the leg and continues with it distally, passes under the extensor retinaculum, and terminates at the ankle in a medial and a lateral branch.

**Muscular branches** are supplied in the leg to the tibialis anterior, extensor digitorum longus, peroneus tertius, and extensor hallucis longus.

An **articular branch** is supplied to the ankle joint.

The **lateral terminal branch** (*external or tarsal branch*) passes across the tarsus deep to the extensor digitorum brevis, and having become enlarged like the dorsal interosseous nerve at the wrist, supplies the extensor digitorum brevis. Three minute interosseous

FIG. 12-69. Deep nerves of the anterior leg.

branches are given off from the enlargement; they supply the tarsal joints and the metatarsophalangeal joints of the second, third, and fourth toes. A muscular filament is sent to the second interosseus dorsalis from the first of these interosseous branches.

The **medial terminal branch** (internal branch) accompanies the dorsalis pedis ar-

tery along the dorsum of the foot, and at the first interosseous space, divides into two dorsal digital nerves (Fig. 12-70) which supply adjacent sides of the great and second toes, communicating with the medial dorsal cutaneous branch of the superficial peroneal nerve. An interosseous branch, given off before it divides, enters the first space, supply-

ing the metatarsophalangeal joint of the great toe and sending a filament to the first interosseus dorsalis.

**SUPERFICIAL PERONEAL NERVE.** The superficial peroneal nerve (musculocutaneous nerve) (Figs. 12-69; 12-70) passes distally between the peronei and the extensor digitorum longus, pierces the deep fascia in the lower third of the leg, and divides into a medial and intermediate dorsal cutaneous nerve.

**Muscular branches** are given off in its course between the muscles to the peroneus longus and brevis.

**Cutaneous filaments** are supplied to the skin of the lower part of the leg.

The **medial dorsal cutaneous nerve** (internal dorsal cutaneous branch) (Fig. 12-69) passes in front of the ankle joint and divides into two dorsal digital branches. The medial one supplies the medial side of the great toe and communicates with the deep peroneal nerve. The lateral one supplies the adjacent sides of the second and third toes. It also supplies the skin of the medial side of the foot and ankle and communicates with the saphenous nerve.

The **intermediate dorsal cutaneous nerve** (external dorsal cutaneous branch) (Fig. 12-69) passes along the lateral part of the dorsum of the foot, supplying the skin of the lateral side of the foot and ankle and communicating with the sural nerve. It terminates by dividing into two dorsal digital branches, one of which supplies the adjacent sides of the third and fourth toes, the other the adjacent sides of the fourth and little toes. Frequently some of the lateral branches of the superficial peroneal nerve are absent and their places are then taken by branches of the sural nerve.

### **Pudendal Plexus**

The **pudendal plexus** (Figs. 12-63; 12-70) is formed from the anterior branches of the second and third and all of the fourth sacral nerves. It is sometimes considered a part of the sacral plexus. It lies in the posterior hollow of the pelvis on the ventral surface of the piriformis muscle.

### **VISCERAL BRANCHES**

The **visceral branches** arise from the second, third, and fourth sacral nerves. They contain (1) parasympathetic visceral efferent

preganglionic fibers, which form synapses with the cells in the small scattered ganglia located in or near the walls of the pelvic viscera, and (2) visceral afferent fibers from the pelvic organs. These nerves join branches of the hypogastric plexus of the sympathetic and the sympathetic chain to form the pelvic plexus, which lies in the deeper portion of the pelvic subserous fascia (Ashley and Anson, 1946).

The various elements of the pelvic plexus cannot be followed by dissection, but the destination of the sacral parasympathetic fibers has been traced by clinical observation and animal experimentation.

The **branches to the bladder, prostate and seminal vesicles** approach these organs from their posterior and lateral sides and terminate in groups of ganglion cells in the pelvic plexus or in the walls of the organs. The postganglionic fibers are efferents to the muscles and glands, except the sphincters, to which they are inhibitory.

The **branches to the uterus** reach the ganglia in the uterine plexus. The postganglionic fibers are inhibitory except during pregnancy, when their function is said to be reversed.

The **branches to the external genitalia** leave the pelvic plexus to join the pudendal nerve. They are distributed through its branches to the corpora cavernosa, causing active dilatation of the cavernous blood sinuses.

The **branches to the alimentary tract** consist of (a) filaments that go directly to the rectum from the pelvic plexus, and (b) fibers that pass through the hypogastric plexus, the hypogastric nerves, and the inferior mesenteric plexus to reach the descending and sigmoid colon. These are preganglionic fibers that have synapses with the cells in the myenteric and submucous plexuses and are efferent to this part of the intestine, except for the sphincter ani internus, to which they are inhibitory.

### **MUSCULAR BRANCHES**

The **muscular branches** (Fig. 12-61), derived mainly from the fourth (sometimes from the third and fifth) sacral, enter the pelvic surfaces of the levator ani and coccygeus. The nerve to the sphincter ani externus (perineal branch) reaches the ischiorectal fossa by piercing the coccygeus or by passing between it and the levator.

FIG. 12-70 Pudendal nerve, and sacral and pudendal plexus of the right side.

### PUDENDAL NERVE

The **pudendal nerve** (*internal pudic nerve*) (Fig. 12-70) arises from S 2, 3 and 4, and passing between the piriformis and coccygeus, leaves the pelvis through the distal part of the greater sciatic foramen. It then crosses the spine of the ischium and reenters the pelvis through the lesser sciatic foramen. It accompanies the internal pudendal vessels along the lateral wall of the ischiorectal fossa in a tunnel formed by a splitting of the obturator fascia (*Alcock's canal*<sup>1</sup>), and as it approaches the urogenital diaphragm, it splits into two terminal branches.

**INFERIOR RECTAL NERVE.** The inferior rectal nerve (*inferior hemorrhoidal nerve*) arises from the pudendal nerve before its terminal division or occasionally directly

from the sacral plexus. Coursing medially across the ischiorectal fossa with the inferior rectal vessels, it breaks up into branches that are distributed to the sphincter ani externus and the integument around the anus. Branches of this nerve communicate with the perineal branch of the posterior femoral cutaneous nerve and with the posterior scrotal nerves.

**PERINEAL NERVE.** The perineal nerve (Fig. 12-70), the larger and more superficial of the two terminal branches of the pudendal, accompanies the perineal artery and at the urogenital diaphragm divides into superficial and deep branches.

The two **superficial branches** of the perineal nerve are the medial and the lateral posterior scrotal (or labial) nerves. They pierce the fascia of the urogenital diaphragm and run ventrally along the lateral part of the urogenital triangle in company with the posterior scrotal branches of the perineal

<sup>1</sup>Benjamin Alcock (1801-?): An Irish professor of anatomy (Cork, then went to America).

artery. They are distributed to the skin of the scrotum in the male or to the skin of the labium majus in the female. The lateral branch communicates with the perineal branch of the posterior femoral cutaneous nerve.

The **deep branch** is mainly muscular, supplying branches to the transversus perinei superficialis, bulbocavernosus, ischiocavernosus, transversus perinei profundus, and sphincter urethrae membranacea. The nerve to the bulb is given off from the nerve to the bulbocavernosus; it pierces this muscle, and supplies the corpus cavernosum urethrae and the mucous membrane of the urethra.

**DORSAL NERVE OF PENIS.** The **dorsal nerve of the penis** (Fig. 12-70), the deeper terminal branch of the pudendal nerve, accompanies the internal pudendal artery along the ramus of the ischium, and then runs ventrally along the margin of the inferior ramus of the pubis, lying between the superficial and deep layers of fascia of the urogenital diaphragm. Piercing the superficial layer, it gives a branch to the corpus cavernosum penis, and continuing forward in company with the dorsal artery of the penis between the layers of the suspensory ligament, it runs along the dorsum of the penis and is distributed to the skin of that organ, ending in the glans penis.

The **dorsal nerve of the clitoris** is smaller and has a distribution corresponding to that of the penis in the male.

### **Coccygeal Plexus**

The **coccygeal plexus** (Fig. 12-63) is formed by the coccygeal nerve with communications from the fourth and fifth sacral nerves. From this delicate plexus, a few fine filaments, the **anococcygeal nerves**, pierce the sacrotuberous ligament and supply the skin in the region of the coccyx.

## **Visceral Nervous System**

The **visceral nervous system** or visceral portion of the peripheral nervous system (vegetative nervous system; involuntary nervous system; major sympathetic system; plexiform nervous system) comprises the whole complex of fibers, nerves, ganglia, and plexuses by means of which impulses are conveyed from the central nervous system to the viscera and from the viscera to

the central nervous system. It has the usual two groups of fibers necessary for reflex connections: (a) afferent fibers, receiving stimuli and carrying impulses toward the central nervous system, and (b) efferent fibers, carrying impulses from the appropriate centers to the active effector organs, which in this instance are the nonstriated muscle, cardiac muscle, and glands of the body.

Attention is called to the use of the term sympathetic system in this edition. In former editions it was used for the visceral nervous system and included both afferent and efferent, autonomic and parasympathetic components. Although the central nervous system is involved in all nervous or reflex control of the viscera, with the possible exception of the enteric plexus, it is more convenient for the purposes of description to separate the peripheral from the central portions. It must be emphasized, however, that the separation is artificial and should not be carried over into physiologic considerations. In the present edition the term sympathetic is used in the restricted meaning of the thoracolumbar division of the visceral efferent system. The terms sympathetic afferent and autonomic afferent are replaced by visceral afferent.

### **VISCERAL AFFERENT FIBERS**

The **visceral afferent fibers** cannot be separated into a morphologically independent system because, like the somatic sensory fibers, their cell bodies are situated in the sensory ganglia of the cerebrospinal nerves. The distinction between somatic and visceral afferent fibers is one of peripheral distribution rather than one of fundamental anatomic and physiologic significance. The visceral afferents, however, commonly have modalities of sensation different from those of somatic afferents, and most of them are either vaguely localized or have no representation in consciousness. The visceral efferent fibers make reflex connections with visceral afferents. The number and extent of the visceral afferents are not clearly established, and the peripheral processes reach the ganglia by various routes. Many traverse the branches and plexuses of the autonomic system, most of them accompany blood vessels for at least a part of their course, and some run in the cerebrospinal nerves.

**REFERRED PAIN.** Although many, perhaps most, of the physiologic impulses carried by visceral afferent fibers fail to reach consciousness, pathologic

conditions or excessive stimulation may activate those that carry pain. The central nervous system has a poorly developed power of localizing the source of such pain, and by some mechanism not clearly understood, the pain may be referred to the region supplied by the somatic afferent fibers whose central connections are the same as those of the visceral afferents. For example, the visceral afferents from the heart enter the upper thoracic nerves, and impulses traversing them may cause painful sensations in the axilla, down the ulnar surface of the arm, and in the precordial region. The study of clinical cases of referred pain has been useful in tracing the path of afferent fibers from the various viscera, and a knowledge of these paths may assist the diagnostician in locating a pathologic process.

The visceral afferent fibers are summarized below; for more complete descriptions of the individual nerves mentioned, consult the accounts given elsewhere.

**HEAD.** Visceral afferents from endings on the peripheral blood vessels of the face and scalp probably accompany the branches of the external carotid artery to the superior cervical ganglion and through communicating rami to the spinal nerves. Afferents on the blood vessels of the brain and meninges may accompany the branches of the internal carotid and vertebral arteries, passing through the upper cervical spinal nerves or possibly the ninth and tenth cranial nerves.

**NOSE AND NASAL CAVITY.** There is evidence that a few visceral afferent fibers from the nose are brought to the brain by the nervus terminalis (Larsell, 1950). Others traverse the branches of the sphenopalatine and palatine nerves to reach the facial nerve through the Vidian and greater superficial petrosal nerves.

**MOUTH AND PHARYNX.** The visceral afferents from the mouth, pharynx, and salivary glands pass through the pharyngeal plexus to the glossopharyngeal, vagus, and facial nerves.

**NECK.** Visceral afferents from the larynx, trachea, esophagus, and thyroid gland are carried by the vagus or reach the sympathetic trunk through the pharyngeal plexus and pass through rami communicantes to the cervical or upper thoracic nerves.

The **carotid sinus nerve** carries the visceral afferents from the pressoreceptor endings in the carotid sinus through the glossopharyngeal nerve. The chemoreceptor afferents from the **carotid body** reach the vagus nerve through branches of the pharyngeal or superior laryngeal nerves.

**THORAX.** The visceral afferents from the thoracic wall and parietal pleura join the intercostal nerves, after following the arteries for variable distances, and thus enter the spinal ganglia. Those from the parietal pericardium join either the phrenic nerve or the intercostal nerves.

Visceral afferents from the **heart** and the origins of the great vessels enter the cardiac plexus and either join the branches of the vagus or reach the upper thoracic spinal nerves and their ganglia by way of sympathetic branches, the sympathetic trunk, and rami communicantes.

The **aortic bodies** (*glomera aortica*) are chemoreceptors similar to the carotid bodies; their afferent fibers run in the right vagus and have cell bodies in the inferior ganglion. The supracardial bodies (aortic paraganglia) are also chemoreceptors with their afferent fibers in the left vagus and cell bodies in the inferior ganglion.

**DEPRESSOR NERVE.** In some animals, the afferent fibers of the vagus from the heart and great vessels are contained in a separate nerve whose stimulation depresses the activity of the heart. In man, these fibers are probably contained in the cardiac branches of the recurrent nerves.

Visceral afferents from the **lungs, bronchi, and pulmonary pleura** reach either the vagus nerve through the pulmonary plexuses or the spinal nerves and their ganglia through the sympathetic branches and rami communicantes.

**ABDOMEN.** Visceral afferent fibers from the **abdominal wall and parietal peritoneum** probably accompany the arteries in part of their course and finally reach the spinal ganglia through the spinal nerves. The myelinated fibers from the Pacinian<sup>1</sup> corpuscles in the mesentery and pancreas at its base run in the thoracic splanchnic nerves, then through the sympathetic trunk, and finally over the white rami communicantes to the spinal nerves and ganglia.

Visceral afferent fibers from the **stomach, small intestine, cecum, appendix, ascending and transverse colon, liver, gallbladder, bile ducts, pancreas, and suprarenals** traverse the celiac plexus and its secondary plexuses and branches. They accompany the arteries, pass through the splanchnic nerves, the

<sup>1</sup>Filippo Pacini (1812-1883): An Italian anatomist (Florence).

sympathetic trunk, and rami communicantes to reach the spinal nerves and ganglia. Some of these afferents may enter the vagus nerve.

The visceral afferents from the **kidney, ureter, testis, ductus deferens, ovary, and uterine tube** traverse the renal and celiac plexuses or parts of their secondary plexuses, pass through the lower thoracic and upper lumbar splanchnic nerves to the sympathetic trunk, and thence through white rami communicantes to the spinal nerves and ganglia.

**PELVIS.** The visceral afferent fibers from the **descending colon, sigmoid, and rectum** traverse the pelvic plexus, hypogastric nerves and plexus, inferior mesenteric plexus, celiac plexus, and lumbar splanchnic nerves on their way to the sympathetic trunk, white rami communicantes, and spinal nerves and ganglia. Others from the rectum pass through the pelvic plexus into the visceral branches of the second, third, and fourth sacral nerves and their ganglia.

Visceral afferents from the **bladder, prostate, seminal vesicles, and urethra** pass through the pelvic plexus and through the hypogastric nerves and plexuses, splanchnic nerves, and sympathetic rami into the lumbar ganglia, or through the visceral branches of the sacral nerves into the sacral ganglia.

Visceral afferents from the **uterus** traverse the pelvic plexus, hypogastric nerves and plexus, lumbar splanchnic nerves, sympathetic trunk, rami communicantes, and lumbar spinal nerves and their ganglia.

Visceral afferent fibers from the **external genitalia** pass through either the pelvic plexus or the pudendal nerve and reach the sacral nerves and their ganglia.

**UPPER EXTREMITY.** Visceral afferent fibers accompany the peripheral blood vessels for some distance, but may join the larger branches of the brachial plexus and reach the dorsal root ganglia through the spinal nerves, or they may follow the paths of the sympathetic fibers and reach the dorsal ganglia, especially the first two or three thoracic, through the white rami communicantes.

**LOWER EXTREMITY.** Visceral afferents accompany the peripheral vessels and the femoral artery to the aortic plexus, then through the lumbar splanchnic nerves to the rami communicantes, spinal nerves and ganglia. Others may join the tibial or peroneal nerves and traverse the sacral and lumbar sym-

pathetic trunk and rami communicantes to reach the lumbar nerves and their ganglia.

## AUTONOMIC OR VISCERAL EFFERENT SYSTEM

The **visceral efferent** portions of the peripheral nervous system are combined into a morphologic and physiologic entity called the **autonomic nervous system** (*systema nervosum autonomicum*) (Fig. 12-71). The fundamental morphologic difference between the visceral and somatic motor systems is that two neurons are required to transmit an impulse from the central nervous system to the active effector organ in the viscera, whereas only a single neuron is required to carry an impulse from the central nervous system to a skeletal muscle fiber. As the name autonomic implies, this system has a certain amount of independence because, in most individuals, it is not under direct voluntary command. It is controlled by neurons within the central nervous system, nevertheless, and is connected with the latter at various levels. The enteric plexus is the only portion of the visceral system that seems to carry out reflex responses without involving the central nervous system (Kuntz, 1953).

The autonomic nervous system is composed of two divisions or systems that differ from each other morphologically and which for the most part are antagonistic to each other physiologically. The morphologic differences have to do (a) with the manner in which the two systems are connected with the central nervous system, and (b) with the location of their ganglia. The **sympathetic** or thoracolumbar system is connected with the central nervous system through the thoracic and upper lumbar segments of the spinal cord, and its ganglia tend to be placed near the spinal column rather than near the viscera innervated. The **parasympathetic** or craniosacral system is connected with the central nervous system through certain cranial nerves and through the middle three sacral segments of the spinal cord, and its ganglia tend to be placed peripherally near the organs innervated.

The sympathetic and parasympathetic systems both innervate many of the same organs, and in this double innervation the two systems are usually antagonistic to each other

**FIG. 12-71** Diagram of efferent autonomic nervous system. Blue, cranial and sacral outflow, parasympathetic. Red, thoracolumbar outflow, sympathetic. Interrupted lines designate postganglionic fibers to spinal and cranial nerves to supply vasomotor innervation to head, trunk and limbs, motor fibers to smooth muscles of skin and fibers to sweat glands. (Modified after Meyer and Gottlieb.) This is only a diagram and does not accurately portray all the details of distribution.

physiologically. No consistent rule can be given for the effect of each, but in general the sympathetic system mobilizes the energy for sudden activity such as that in rage or flight; for example, the pupils dilate, the heart beats faster, the peripheral blood vessels constrict, and the blood pressure rises. The parasympathetic system aims more toward restoring the reserves; for example, the pupils contract, the heart beats more slowly, and the alimentary tract and its glands become active.

The two systems frequently travel together, especially in the thorax, abdomen, and pelvis, forming extensive plexuses that contain the fibers of both. The arrangement of the bundles within these plexuses is very complicated and the identity of individual fibers cannot be determined with certainty. For purposes of description, therefore, a third subdivision of the autonomic system is recognized—the great autonomic plexuses.

### **Parasympathetic System**

The parasympathetic system is the **cranio-sacral portion** of the **autonomic nervous system** and contains visceral efferent fibers that originate in certain cranial nerves and in the sacral portion of the spinal cord.

#### **CRANIAL PORTION OF THE PARASYMPATHETIC SYSTEM**

The **cranial outflow** includes fibers in the oculomotor, facial, glossopharyngeal, and vagus nerves. These nerves have been described previously and the details are repeated here only insofar as they apply to the visceral efferent fibers.

**OCULOMOTOR NERVE.** The oculomotor nerve contains efferent fibers for the nonstriated muscle making up the ciliaris and sphincter pupillae muscles of the eyeball (for diagram, see Fig. 12-5). The preganglionic fibers arise from the cells in the Edinger-Westphal nucleus<sup>1,2</sup> located in the anterior part of the oculomotor nucleus in the tegmentum of the midbrain. They run in the inferior division of the oculomotor nerve to the ciliary gan-

glion (Fig. 12-6) and there form synapses with the ganglion cells. The postganglionic fibers proceed in the short ciliary nerves to the eyeball, penetrate the sclera, and reach the muscles just named.

**FACIAL NERVE.** The facial nerve contains efferent fibers for the lacrimal gland, the submandibular and sublingual glands, and the many small glands in the mucous membrane of the nasal cavity, palate, and tongue (for diagrams, see Figs. 12-16; 12-17). The preganglionic fibers arise from cells in the superior salivatory nucleus in the reticular formation, dorsomedial to the facial nucleus in the pons, and leave the brain in the *nervus intermedius*.

**Pterygopalatine Ganglion.** Certain preganglionic fibers branch from the facial nerve at the geniculum via the greater petrosal nerve, course through the pterygoid canal, and terminate by forming synapses with the cells in the pterygopalatine ganglion (Fig. 12-12). Some of the postganglionic fibers reach the **lacrimal gland** via the maxillary, zygomatic, and lacrimal nerve route; others accompany the branches of the maxillary nerve to the **glands in the mucous membrane of the nasal cavity and nasopharynx**; and still others accompany the palatine nerves to the **glands of the soft palate, tonsils, uvula, roof of the mouth, and upper lip**.

**Submandibular Ganglion.** Other preganglionic fibers leave the facial nerve in the chorda tympani and with it join the lingual nerve to reach the submandibular ganglion (Fig. 12-12). They form synapses in the ganglion or with groups of ganglion cells in the substance of the gland. The postganglionic fibers form the secretomotor supply to the **submandibular and the sublingual glands**.

**Otic Ganglion.** Filaments communicating with the **otic ganglion** may contribute preganglionic fibers which join those from the glossopharyngeal nerve to supply the parotid gland.

**GLOSSOPHARYNGEAL NERVE.** The glossopharyngeal nerve contains efferent fibers for the parotid gland and small glands in the mucous membrane of the tongue and floor of the mouth (for diagram, see Fig. 12-21). The preganglionic fibers arise in the inferior salivatory nucleus in the medulla oblongata, traverse the tympanic and lesser petrosal nerves, and form synapses in the **otic ganglion** (Fig. 12-12). Most of the post-

<sup>1</sup>Ludwig Edinger (1855–1918): A German neurologist and anatomist (Frankfurt-am-Main).

<sup>2</sup>Karl Friedrich Otto Westphal (1833–1890): A German psychiatrist and anatomist (Berlin).

ganglionic fibers join the auriculotemporal nerve and are distributed with its branches to the **parotid gland**, providing its secretomotor fibers. Other postganglionic fibers are said to supply the glands of the mucous membrane of the tongue and floor of the mouth.

**VAGUS NERVE.** The vagus nerve contains efferent fibers for the nonstriated muscle and glands of the bronchial tree, of the alimentary tract as far as the transverse colon, of the gallbladder and bile ducts, the pancreas, and inhibitory fibers for the heart. The preganglionic fibers arise from cells in the dorsal motor nucleus of the vagus in the medulla oblongata; they run in the vagus nerve and its branches to ganglia situated in or near the organs innervated.

**Heart.** The preganglionic fibers for the heart reach the cardiac plexus by way of the superior and inferior cardiac nerves of the vagus, and are distributed by branches of the plexus to the ganglion cells in the heart wall (Fig. 12-77). The ganglion cells form numerous clusters in the connective tissue of the epicardium on the surface of the atrium, on the auricular appendages, and in the interatrial septum. The postganglionic fibers terminate in relation to specialized muscular elements in the sinoatrial and atrioventricular nodes, and atrioventricular bundle and its branches as far as the Purkinje<sup>1</sup> fibers (Stotler and McMahon, 1947).

**Lungs.** The preganglionic fibers from the bronchi leave the main trunk of the vagus nerve in the thorax as the anterior and posterior bronchial branches. They traverse the anterior and posterior pulmonary plexuses (Figs. 12-24; 12-25) and terminate in the clusters of ganglion cells scattered along the ramifications of the bronchial tree. The postganglionic fibers are distributed to the bronchial musculature and bronchial glands.

**Alimentary Tract.** The alimentary tract receives, through various branches, preganglionic fibers that end in the **myenteric plexus** of Auerbach and the **submucous plexus** of Meissner, forming synapses with the ganglion cells scattered in groups throughout these plexuses. The postganglionic fibers are the efferents from the muscular walls and the secreting cells of the tunica mucosa.

The preganglionic fibers reach the upper part of the **esophagus** through the recurrent nerve, and the lower part, below the hilum of the lung, through branches from the esophageal plexus (Fig. 12-76).

The **stomach** receives an average of four branches from the anterior vagus and six from the posterior vagus. The pylorus and duodenum receive fibers from the hepatic branch of the anterior vagus.

The **small intestine, cecum, appendix vermiformis, ascending and transverse colon** receive fibers from the posterior vagus that join the celiac plexus (Fig. 12-80) and accompany the branches of the superior mesenteric artery (Jackson, 1949).

The **gallbladder and bile ducts** receive preganglionic fibers through the vagus branches in the celiac plexus, which traverse the gastrohepatic ligament and terminate in the small clusters of ganglion cells in the wall of the gallbladder and in the region adjacent to the bile ducts. The postganglionic fibers are the efferents for the muscular walls and mucous membrane.

The **pancreas** receives fibers through the hepatic branches of the anterior and posterior vagi and, through the branches of the celiac plexus that accompany the arteries, supply this organ.

#### SACRAL PORTION OF THE PARASYMPATHETIC SYSTEM

The cells that give rise to the sacral outflow are in the second, third, and fourth sacral segments of the spinal cord and pass out with the corresponding sacral nerves. They leave the sacral nerves in the visceral branches and join the pelvic plexus (Fig. 12-81) in the deeper portions of the pelvic subserous fascia. Branches from this plexus contain preganglionic fibers for the scattered ganglia in or near the walls of the various pelvic viscera (Ashley and Anson, 1946).

The branches to the **bladder, prostate and seminal vesicles** supply efferent fibers to these organs, except for the fibers to the sphincter, which are inhibitory.

The branches to the **uterus and vagina** reach ganglia in the uterovaginal plexus; the postganglionic fibers are inhibitory except during pregnancy, when their function is said to be reversed.

The branches of the **pelvic plexus**, which join the pudendal nerve and are distributed

<sup>1</sup>Johannes Evangelista Purkinje (1787-1869): A Bohemian anatomist and physiologist (Breslau and Prague).

to the **external genitalia**, cause active dilatation of the cavernous blood sinuses of the erectile corpora.

The visceral branches of the sacral nerves in laboratory animals are concentrated in a single trunk called the "**nervus erigens**" because of this function, but the term is not directly applicable to the conditions in man because there is no single nerve such as that used for experimentation in the animals.

Branches from the **pelvic plexus** containing preganglionic fibers join the **hypogastric nerve**, and through it and the inferior mesenteric plexus are distributed to the **descending** and **sigmoid colon** and **rectum**. They are efferent to this part of the intestine except for the sphincter ani internus, for which they are inhibitory. Small branches from the pelvic plexus go directly to the rectum.

### **Sympathetic System**

The **sympathetic system** (Fig. 12-72) receives its fibers that connect with the central nervous system through the **thoracolumbar outflow** of visceral efferent fibers. These fibers are the axons of cells in the lateral column of gray matter in the thoracic and upper lumbar segments of the spinal cord. They leave the cord through the ventral roots of the spinal nerves and traverse short communications to reach the sympathetic trunk, where they may terminate in the chain ganglia of the trunk itself, or may continue into the collateral ganglia of the prevertebral plexuses. They are the preganglionic fibers and are mostly the small myelinated variety (3  $\mu\text{m}$  or less in diameter). The postganglionic fibers are the axons of the cells in these chain and collateral ganglia and are generally unmyelinated. They are distributed to the heart, nonstriated muscle, and glands all over the body, which they reach by way of communications with the cerebrospinal nerves, by way of various plexuses, and by their own visceral branches of distribution.

**VARIATIONS.** Variability is a prominent characteristic of the sympathetic system, and although a description that will correspond with even the majority of individuals is impossible, certain general principles of organization can be recognized. These are incorporated in the account that follows and the general description is supplemented and made specific by giving a few of the common variations. Many of the details concerning the paths taken by

the fibers are still unknown, and we must rely heavily upon information obtained from animal experimentation, although it may not have been confirmed by clinical observations with human patients.

**SYMPATHETIC TRUNK.** The **sympathetic trunk** consists of a series of ganglia called the central or chain ganglia (Fig. 12-76), which are connected by intervening cords, and extend along the lateral aspect of the vertebral column from the base of the skull to the coccyx. The cranial end of the trunk proper is formed by the superior cervical ganglion (Fig. 12-72), but there is a direct continuation into the head, the internal carotid nerve. The caudal ends of the two trunks converge at the coccyx and may merge into a single ganglion—the **ganglion impar**. Cross connections between the two cords in the sacral region are frequent, but rarely occur above the fifth lumbar.

The trunk contains, in addition to the ganglia, the preganglionic fibers, which are small (1 to 3  $\mu\text{m}$  in diameter) and myelinated; the postganglionic fibers, which are mostly unmyelinated; and a smaller number of afferent fibers, which are both myelinated (medium, 5  $\mu\text{m}$ , and large, 10  $\mu\text{m}$ ) and unmyelinated. All types of fibers may run up or down in the trunk for the distance between two or many segments. The cords intervening between the ganglia are usually single except in the lower cervical region, but doubling is frequent in any part of the trunk although it rarely extends farther than between two adjacent ganglia. Numerous small collections of ganglion cells occur outside of the major ganglia; these may be microscopic in size or grossly visible. They are called **intermediary ganglia**, and are found in the roots or branches of the trunk and even in the spinal nerves close to these communicating rami (Kuntz and Alexander, 1950).

**GANGLIA.** The **central or chain ganglia** of the sympathetic trunk are rounded, fusiform or irregular in shape, with diameters usually ranging from 1 to 10 mm, but neighboring ganglia may fuse into larger masses and the superior cervical ganglion is always larger. They contain multipolar neurons whose processes are the postganglionic fibers.

The **roots** of the ganglia of the sympathetic trunk are commonly called the **white rami communicantes** (*rami communicantes albi*) because of the whitish color imparted to

**Fig. 12-72.** The right sympathetic chain and its connections with the thoracic, abdominal, and pelvic plexuses. (After Schwalbe.)

them by the preponderance of myelinated fibers they contain. These myelinated fibers are mainly the small (1 to 3  $\mu\text{m}$  in diameter) preganglionic axons of the thoracolumbar outflow, whose cell bodies are in the lateral

column of gray matter in the spinal cord. They emerge from the spinal cord with the somatic motor fibers in the ventral roots of the spinal nerves of the thoracic and the first and second lumbar segments. Many of the

preganglionic fibers in each root fail to make synaptic connections in the ganglia at the level of entrance; some travel cranialward to the cervical ganglia, some caudalward to the lumbar and sacral ganglia, and many in the lower thoracic and upper lumbar levels pass out of the trunk and reach the celiac and related collateral ganglia through the splanchnic nerves. One preganglionic fiber may give collaterals to several of the chain ganglia and may terminate on as many as 15 to 20 ganglionic neurons.

The roots of the ganglia or white rami communicantes are to be distinguished from the branches to the spinal nerves or gray rami communicantes with which they are closely related. The white rami leave the anterior primary divisions of the spinal nerves close outside of the intervertebral foramina, but are regularly more distal than the gray rami. They contain medium and large myelinated fibers, probably afferents, and some unmyelinated fibers in addition to the small myelinated preganglionic fibers. In the lower thoracic and upper lumbar regions the white rami take an oblique course from the nerve of one segment to the ganglion of the segment below and have been called, therefore, the oblique rami, as opposed to the transverse gray rami. They are more likely to be attached to the intervening cords than the gray rami. The white rami, varying from 0.5 to 2 cm, are longer in the lower thoracic and lumbar region, where they are also usually double or triple.

The sympathetic trunk has branches of distribution, containing the postganglionic fibers that originate in the ganglia, and branches of communication, containing preganglionic fibers that pass through the trunk without synapses on their way to the collateral ganglia in the abdomen.

**BRANCHES OF DISTRIBUTION.** The branches of distribution are of several types: (1) branches to the spinal nerves, (2) branches to the cranial nerves, (3) branches accompanying arteries, (4) separate branches to individual organs, and (5) branches to the great autonomic plexuses.

1. The branches to the **spinal nerves** are commonly called the **gray rami communicantes** (Fig. 12-73) because the preponderance of unmyelinated fibers gives them a more grayish cast than the roots or white rami, which are adjacent to them in the thoracic area. These branches contribute postganglionic fibers, most of which accompany the cutaneous branches of the spinal nerves to supply the arrectores pilorum muscles, the sweat glands, and the vasoconstrictor fibers of the peripheral blood vessels.

Gray rami join all the spinal nerves, while the white rami arise only from the thoracic and first two lumbar segments. The gray ramus usually leaves the

**Fig. 12-73.** Schema showing structure of a typical spinal nerve. Afferent, blue; efferent, red.

trunk at a ganglion near the same level as the spinal nerve, and in the thoracic and lumbar regions, where there are both gray and white rami, it is regularly proximal to the white.

Branches to the **cranial nerves** may go directly to the nerves or they may pass through plexuses on blood vessels. Direct communications are encountered to the superior and inferior ganglia of the vagus, the inferior ganglion of the glossopharyngeal, and the hypoglossal nerves.

Branches accompanying the **arteries** are too numerous to list here, but are given with the detailed descriptions of the different parts of the system in later pages. Prominent examples are the nerves on the internal and external carotid arteries and their branches.

Branches to **individual organs** may take an independent course but they commonly pass through plexuses (for example, the cardiac branches), or accompany blood vessels for some distance (for example, those to the bulb of the eye).

Branches to the **cardiac, pulmonary, and pelvic plexuses** probably contain postganglionic fibers, but most of the branches from the trunk to the abdominal plexuses probably contain preganglionic fibers.

**BRANCHES OF COMMUNICATION.** The principal branches of communication containing preganglionic fibers are the **splanchnic nerves**. They branch from the ganglia or the trunk of the thoracic and lumbar regions and supply the fibers that are the roots to the celiac, aorticorenal, and mesenteric ganglia. The postganglionic fibers from these ganglia supply the various abdominal and pelvic organs.

## DIVISIONS OF THE SYMPATHETIC SYSTEM

The sympathetic nervous system is divided into portions according to topographic position as follows: (1) cephalic, (2) cervical, (3) thoracic, (4) abdominal or lumbar, and (5) pelvic. These parts are not independent and are chosen merely for convenience in description. In addition to these portions, concerned primarily with the sympathetic trunk and ganglia, there are autonomic plexuses, which are described separately.

### Cephalic Portion of the Sympathetic System

The **cephalic portion** of the sympathetic system contains no part of the ganglionated cord, but is formed largely by a direct ce-

phalic prolongation from the superior cervical ganglion, named the internal carotid nerve. In addition, there are nerves accompanying the vertebral artery and the various branches of the external carotid artery that supply fibers to many structures in the head, such as the pilomotor muscles, sweat glands, and peripheral arteries of the face, and the salivary and other glands.

**INTERNAL CAROTID NERVE.** The internal carotid nerve (Fig. 12-23), arising from the cephalic end of the superior cervical ganglion, accompanies the internal carotid artery, and after entering the carotid canal in the petrous portion of the temporal bone, divides into two branches that lie against the medial and lateral aspects of the artery. The lateral branch, the larger of the two, distributes filaments to the carotid artery and forms the internal carotid plexus. The medial branch also distributes filaments to the artery, and following the artery to the cavernous sinus, forms the cavernous plexus.

**Internal Carotid Plexus.** The internal carotid plexus (carotid plexus) (Fig. 12-21) is the continuation of the lateral branch of the internal carotid nerve. It surrounds the lateral aspect of the artery, occasionally containing a small carotid ganglion. In addition to filaments to the artery, it has the following branches:

A **communication** with the **trigeminal nerve** joins the latter at the trigeminal ganglion.

A **communication** joins the **abducent nerve** as it lies near the lateral aspect of the internal carotid artery.

The **deep petrosal nerve** (Fig. 12-9) leaves the plexus at the lateral side of the artery, passes through the cartilage of the auditory tube which fills the foramen lacerum, and joins the greater petrosal nerve to form the nerve of the pterygoid canal (Vidian nerve). In the pterygopalatine fossa, the Vidian nerve joins the pterygopalatine ganglion, and its contribution through the deep petrosal nerve has been called the sympathetic root of the ganglion. However the sympathetic fibers, already postganglionic, pass through or beside the ganglion without synapses and are distributed to the glands and blood vessels of the pharynx, nasal cavity, and palate by accompanying the branches of the maxillary nerve (Fig. 12-16).

The **caroticotympanic nerves** are two or three filaments that pass through foramina in the bony wall of the carotid canal and join

the tympanic plexus on the promontory of the middle ear.

**Cavernous Plexus.** The cavernous plexus (Fig. 12-12) is the continuation of the medial branch of the internal carotid nerve. It lies inferior and medial to the part of the internal carotid artery enclosed by the cavernous sinus. It communicates with the adjacent cranial nerves and continues along the artery to its terminal branches.

The communication with the **oculomotor nerve** enters the orbit and joins the nerve at its point of division.

A communication joins the **trochlear nerve** as it lies in the lateral wall of the cavernous sinus.

The communication with the **ophthalmic division** of the **trigeminal** joins the latter nerve at its inferior surface.

Fibers to the **dilator pupillae muscle** of the iris traverse the communication with the ophthalmic nerve and accompany the nasociliary nerve and the long ciliary nerves to the posterior part of the bulb, where they penetrate the sclera and run forward to the iris (for diagram, see Fig. 12-4).

The communication with the **ciliary ganglion** leaves the anterior part of the cavernous plexus and enters the orbit through the superior orbital fissure. It may join the nasociliary nerve and reach the ganglion through the latter's branch to the ganglion, or it may take an independent course to the ganglion.

Filaments to the **hypophysis** accompany its blood vessels.

The **terminal filaments** from the internal carotid and cavernous plexuses continue along the anterior and middle cerebral arteries and the ophthalmic artery. Fibers on the cerebral arteries may be traced to the pia mater; those on the ophthalmic artery accompany all its branches in the orbit. The filaments on the anterior communicating artery may connect the sympathetic nerves of the right and left sides.

**External Carotid Nerves.** The external carotid nerves send filaments out along all the branches of the external carotid artery. The filaments on the facial artery join the **submandibular ganglion**; they have formerly been called the sympathetic root of the ganglion, but they pass through it without forming synapses and supply the submandibular and probably the sublingual glands (for diagram, see Fig. 12-17). The network of filaments on the middle meningeal artery gives

off the **small deep petrosal nerve**, which has been called the sympathetic root of the **otic ganglion**, but its fibers pass through the ganglion without synapses, some accompanying the auriculotemporal nerve to the parotid gland (for diagram, see Fig. 12-19), others forming the **external superficial petrosal nerve** which is a communication with the geniculate ganglion. Filaments on the facial, superficial temporal, and other arteries that are distributed to the skin supply the arrectores pilorum muscles and sweat glands, as well as the muscles constricting the arteries themselves.

### Cervical Portion of the Sympathetic System

The **cervical portion** of the sympathetic trunk consists of three ganglia—superior, middle, and inferior—connected by intervening cords (Fig. 12-74). It is ventral to the transverse processes of the vertebrae, close to the carotid artery, being embedded in the fascia of the carotid sheath itself or in the connective tissue between the sheath and the longus colli and capitis muscles. It receives no roots or white rami communicantes from the cervical spinal nerves; its preganglionic fibers enter the trunk through the white rami from the upper five thoracic spinal nerves, mainly the second and third, and travel cranialward in the trunk to the three ganglia. The trunk also contains postganglionic fibers from various sources and visceral afferent fibers with their cell bodies in the dorsal root ganglia.

**SUPERIOR CERVICAL GANGLION.** The **superior cervical ganglion** (Fig. 12-22), much larger than the other cervical ganglia and usually the largest of all the trunk ganglia, is approximately 28 mm long and 8 mm wide, fusiform in shape, frequently broad and flat, and occasionally constricted into two or more parts. It is embedded in the connective tissue between the carotid sheath and the prevertebral fascia over the longus capitis, at the level of the second cervical vertebra. It is the cephalic end of the sympathetic chain and is connected with the middle ganglion caudally by a rather long interganglionic cord. It is believed to be formed by the coalescence of sympathetic primordia from the cranial four cervical segments of the body. Its branches follow.

**Internal and External Carotid Nerves.** The internal and external carotid nerves (described previously) leave the cephalic pole

**Fig. 12-74.** Cervical portion of the sympathetic nervous system on the right side, with the common carotid artery and internal jugular vein removed and with the vagus nerve and thyroid gland drawn aside. (Redrawn from Töndury.)

of the ganglion, and serve as direct continuations of the sympathetic trunk into the head.

**Cranial Nerves.** Communications with the cranial nerves are delicate filaments that join (a) the inferior ganglion of the glossopharyngeal nerve, (b) the superior and inferior ganglia of the vagus, and (c) the hypoglossal nerve. The jugular nerve is a filament that passes cranialward to the base of the skull and divides to join the inferior ganglion of the glossopharyngeal and the superior ganglion of the vagus nerve.

**Cervical Nerves.** Branches to the upper two to four cervical spinal nerves are the **gray rami communicantes** of these nerves. They course lateralward and dorsalward,

and have been called the lateral or external branches of the ganglion. The branches to any one nerve are variable and may be multiple or absent.

**Variations.** The branches to the **first** and **second** nerves are constantly present. Since the spinal nerves in the neck are connected by loops, as parts of the cervical plexus, the branch to the first nerve may join the loop between the first and second nerves, and the branch to the second may join the loop between the second and third nerves. There may be two to four branches to each of these nerves.

The **third** cervical nerve receives a branch (ramus) from the ganglion in the majority of individuals, but in many instances it comes from the trunk below the superior ganglion. A branch for the third

nerve often forms a loop with a lower branch, which then supplies roots to both the third and fourth nerves. Branches may join the third nerve itself or the loop between it and the fourth nerve.

The **fourth nerve** receives a branch from the ganglion only occasionally. Its rami frequently arise in common with those of either the third, fifth, or even the sixth nerves, and may come from the trunk or from nerves accompanying the vertebral artery.

**Pharyngeal Branches.** Pharyngeal branches, commonly four to six, leave the medial aspect of the ganglion, and in their course toward the pharynx, communicate with pharyngeal branches of the glossopharyngeal and vagus nerves opposite the constrictor pharyngis medius to form the **pharyngeal plexus**. Some of the filaments form a plexus on the lateral wall of the pharynx, others travel in the substance of the prevertebral fascia to the dorsum of the pharynx and form a posterior pharyngeal plexus. Filaments communicate with the superior laryngeal nerve.

**Intercarotid Plexus.** The intercarotid plexus receives one or two branches, either from the ganglion or from the external carotid nerves. They communicate with filaments from the pharyngeal branch of the vagus and the carotid branch of the glossopharyngeal nerve in the region of the carotid bifurcation, and are distributed in the plexus to the carotid sinus and the carotid body, where they probably serve a vasomotor function.

**Superior Cardiac Nerve.** The superior cardiac nerve (Figs. 12-74; 12-75) arises by two or three filaments from the ganglion, and occasionally also by a filament from the trunk between the superior and middle ganglia. It runs down the neck in the connective tissue of the posterior layers of the carotid sheath superficial to the longus colli, and crosses ventral or dorsal to the inferior thyroid artery and recurrent nerve. The course of the nerves on the two sides then differs. The **right nerve**, at the root of the neck, passes either ventral or dorsal to the subclavian artery, and along the brachiocephalic artery to the deep part of the cardiac plexus. The **left nerve** passes ventral to the common carotid and across the left side of the arch of the aorta to reach the superficial part of the cardiac plexus. The superior cardiac nerves may communicate with the middle and inferior cardiac sympathetic nerves, with the cardiac branches of the vagus, the external branch of the superior laryngeal nerve, the

recurrent nerve, the thyroid branch of the middle ganglion, the nerves on the inferior thyroid artery, and the tracheal and anterior pulmonary plexuses.

**MIDDLE CERVICAL GANGLION.** The middle cervical ganglion (Fig. 12-75), the smallest of the three cervical ganglia, varies in size, form, and position, and may be either absent or doubled. It probably represents a fusion of the two sympathetic primordia corresponding to the fifth and sixth cervical nerves. When single, the ganglion may have a high position, at the level of the transverse process of the sixth cervical vertebra (the **carotid** or *Chassaignac's tubercle*<sup>1</sup>), or a low position nearer the level of the seventh cervical vertebra. In the high position it lies on the longus colli above the cranial bend of the inferior thyroid artery. In the low position it lies in close association with the ventral or ventromedial aspect of the vertebral artery, 1 to 3 cm from the latter's origin. The middle cervical ganglion has no white ramus communicans; its preganglionic fibers probably leave the spinal cord through the white rami of the second and third thoracic nerves and reach the ganglion through the intervening sympathetic trunk.

**Variations.** The middle cervical ganglion was absent in 5, single in 10 and double in 10 of 25 dissections (Pick and Sheehan, 1946). It was present in 53 and double in two of 100 body halves (Jamieson *et al.*, 1952), with 64% in the high position. A small ganglion in the low position may have no branches. Several small thickenings may occur along the trunk between the superior and inferior ganglia. The ganglion may be split, surrounding the inferior thyroid artery (Axford, 1928).

The **intermediate cervical sympathetic ganglion** (of Jonnesco, 1923) corresponds to a middle ganglion in the low position described above. According to Saccomanno (1943), it appears more constantly than a middle ganglion in the high position. A ganglion in the low position has been called the **thyroid ganglion** because of its close relationship to the inferior thyroid artery (Jamieson *et al.*, 1952). The **vertebral ganglion** is a name given to a ganglion in the low position, on the deep part of the loop of the ansa subclavia, included as part of the stellate ganglionic configuration (Pick and Sheehan, 1946).

**Cervical Nerves.** The branches (gray rami communicantes) are constantly supplied to the fifth and sixth nerves. A ganglion in the

high position may send branches to the fourth nerve.

The gray rami of the **fifth cervical nerve** number from one to three. (1) The most constant arises from the middle ganglion or the trunk just above it, runs upward and laterally across the scalenus anterior, winds around the carotid tubercle and along a groove in the transverse process of the fifth cervical vertebra to the fifth nerve. It may pierce the scalenus anterior and it may divide, one branch going to the sixth nerve, or it may be prolonged to give a branch to the fourth or even the third nerve (Axford, 1928). (2) A ramus present in the majority of individuals leaves the trunk just above the ca-

rotid tubercle, pierces the longus colli either medial or lateral to the vertebral artery, and receives a communication from the nerve of the vertebral artery. (3) An inconstant ramus is a branch of that of the sixth nerve which accompanies the vertebral artery.

The rami of the **sixth cervical nerve** may be two to four in number, one from the middle and one from the inferior ganglion being constant. (1) A short ramus from the middle ganglion runs cranialward through the longus colli just above the carotid tubercle to join the sixth nerve as it lies in its groove, medial to the vertebral artery. (2) A long fine branch from the middle ganglion or the trunk just above it crosses the vertebral ar-

tery and scalenus anterior and joins the nerve lateral to the carotid tubercle, sometimes continuing on to the fifth nerve.

**Middle Cardiac Nerve.** The middle cardiac nerve (great cardiac nerve) (Fig. 12-75), the largest of the three cardiac nerves in the neck, arises from the middle cervical ganglion, from the trunk between the middle and inferior ganglia, or both. As it descends dorsal to the common carotid artery, it communicates with the superior cardiac nerve and the inferior laryngeal nerve. On the right side, at the root of the neck, it goes either deep or superficial to the subclavian artery, continues along the trachea, communicates with the recurrent nerve, and joins the right side of the deep part of the cardiac plexus. The left nerve enters the thorax between the common carotid and subclavian arteries and joins the left side of the deep part of the cardiac plexus.

**Thyroid Nerves.** Branches from the middle cervical ganglion form a plexus on the inferior thyroid artery, supply the thyroid gland, join the plexus on the common carotid artery, and may communicate with the inferior laryngeal and external branch of the superior laryngeal nerves (Braeucker, 1922).

The trunk between the middle and inferior cervical ganglia is constantly double, the two strands enclosing the subclavian artery. The superficial strand is usually much longer than the deep strand and forms a loop about the artery, supplying it with branches; it is called the **ansa subclavia** (of Vieussens<sup>1</sup>) (Fig. 12-75). Since it is a rather constant feature, it may be used to identify and distinguish the middle and inferior ganglia or the components representing them. Occasionally the loop is formed about the vertebral artery instead of the subclavian, or there may be individual loops about both.

**INFERIOR CERVICAL GANGLION.** The inferior cervical ganglion (Fig. 12-75) is situated between the base of the transverse process of the seventh cervical vertebra and the neck of the first rib, on the medial side of the costocervical artery. In most instances it is incompletely separated from or fused with the first thoracic ganglion, but it will be described as it appears when discrete, and the fused ganglion, called the stellate, also will be described below. It is larger than the mid-

dle ganglion, has an irregular shape, and probably represents the fusion of sympathetic primordia corresponding to the seventh and eighth cervical nerves. It has no white ramus, but receives its preganglionic fibers from the thoracic part of the trunk through its connection with the first thoracic ganglion.

**Variations.** The inferior cervical ganglion was independent in 5 out of 25 cases (Pick and Sheehan, 1946) and in 18 out of 100 cases (Jamieson et al., 1952). A white ramus has been described joining the eighth cervical nerve and the sympathetic (Pearson, 1952).

**Cervical Nerves.** Branches (gray rami communicantes) are constantly supplied to the sixth, seventh, and eighth cervical nerves.

The sixth cervical nerve commonly receives branches from the inferior cervical ganglion as well as from the middle cervical ganglion. (1) A constant, rather thick ramus from the deep part of the inferior cervical ganglion runs cranialward along the medial aspect of the vertebral artery, ventral to the vertebral veins and lateral to the longus colli, and enters the foramen in the transverse process of the sixth cervical vertebra with the vertebral artery. It communicates with the plexus on the vertebral artery and supplies rami for the sixth and seventh, sometimes the fifth or even more cephalic nerves. (2) An inconstant ramus from the inferior ganglion is similar to the last, but pierces the scalenus anterior instead of passing through the foramen (Axford, 1928).

The seventh cervical nerve receives two to five branches (gray rami) from the inferior cervical ganglion. (1) A constant, well-defined branch 15 to 25 mm long crosses ventral to the eighth cervical nerve, either deep to, superficial to, or piercing the scalenus anterior. It may be composed of two or three parallel filaments. (2) A constant branch accompanies the vertebral artery and is shared by the sixth nerve. (3) A frequent branch lies close to the vertebral vein, crosses the eighth cervical nerve, to which it may give filaments, and enters the foramen in the seventh cervical vertebra with the vein (Axford, 1928).

The eighth cervical nerve receives two to five rather short branches (averaging 10 mm in length) from the inferior cervical ganglion. (1) A constant, well-defined, thick branch runs cranialward and lateralward, often across the neck of the first rib, and joins the eighth cervical nerve deep to the scalenus anterior. It is dorsal to the first part of the subclavian artery and is intimately related to the superior intercostal artery. It may be represented by two to four parallel filaments. (2) A constant short thick branch from the upper pole of the inferior ganglion runs

<sup>1</sup>Raymond de Vieussens (1641-1715): A French anatomist (Montpellier).

vertically cranialward, medial and dorsal to the vertebral artery, a few millimeters lateral to the longus colli. It passes ventral to the transverse process of the first thoracic vertebra and medial to the first costocentral articulation, and joins the eighth cervical nerve as it emerges from its foramen. (3) A frequent ramus accompanies the vertebral vein with a similar branch to the seventh nerve.

**Inferior Cardiac Nerve.** The inferior cardiac nerve (Fig. 12-75) arises from either the inferior cervical ganglion, the first thoracic ganglion, the stellate ganglion, or the ansa subclavia. It passes deep to the subclavian artery and along the anterior surface of the trachea to the deep cardiac plexus. It communicates with the middle cardiac nerve and the recurrent laryngeal nerve, and supplies twigs to various cervical structures (Saccomanno, 1943).

**Vertebral Nerve.** The branches that accompany the vertebral artery through the vertebral foramina are large. They join similar branches from the first thoracic ganglion to form the vertebral nerve, which continues into the cranial cavity on the basilar, posterior cerebral, and cerebellar arteries. Communications between the vertebral nerve and the cervical spinal nerves frequently serve as rami of these nerves (Christensen et al., 1952).

### Junction of Cervical and Thoracic Portions

The junction of the cervical with the thoracic portion of the sympathetic trunk requires special consideration, first, because the lowest cervical and highest thoracic ganglia are usually fused, and second, because the trunk makes an abrupt change of direction at this point. The cervical portion of the trunk lies upon the ventral aspect of the transverse processes, but is also in a plane ventral to the vertebral bodies because of the latter's small size and the presence of the longus colli muscle. The trunk drops back dorsalward as it enters the thorax, winding around the transverse process of the seventh cervical vertebra to reach the neck of the first rib.

**STELLATE GANGLION.** The stellate ganglion (cervicothoracic ganglion) (Fig. 12-75) is the name given to the ganglionic mass that results when, as is usually the case, the inferior cervical and first thoracic ganglia are fused. It varies in size and form, occasionally including the middle cervical or the second

thoracic ganglia, and is located between the eighth cervical and first thoracic nerves. Its branches and communications are modifications of those that would be found if the component ganglia remained separate. The white ramus communicans, therefore, comes from the first thoracic nerve, or from the second also, if the mass includes the second ganglion.

The branches of the stellate ganglion that supply the gray rami to the spinal nerves include: a frequent branch to the sixth nerve, a constant branch to the seventh nerve, and constant double or multiple branches to the eighth cervical, first thoracic, and second thoracic nerves. The large branch to the vertebral artery leaves the superior border of the ganglion and forms the major portion of the vertebral nerve. Other branches are similar to those described for the independent ganglia (Kirgis and Kuntz, 1942).

**Variations.** In 25 bodies, the inferior cervical ganglion was independent in 5, fused with the first thoracic in 17, and fused with both the first and second thoracic in 3 (Pick and Sheehan, 1946). A stellate ganglion was present in 82 of 100 bodies (Jamieson et al., 1952). When the second thoracic is fused with the first, the inferior cervical is more likely to be independent.

**Surgical Considerations.** The branches (gray rami) from the stellate ganglion to the eighth cervical and first thoracic nerves carry the bulk of the sympathetic fibers to the upper limb (Kirgis and Kuntz, 1942). Other branches also carry fibers, however, and Woollard and Norish (1933) recommend that the middle cervical and second thoracic ganglia be included in the "stellate complex," and that the description of the independent ganglia be abandoned. The sympathetic rami of the brachial plexus are described in more detail in the discussion of the brachial plexus.

**Comparative Anatomic Considerations.** The stellate ganglion in cats includes the inferior cervical and first three thoracic ganglia (Saccomanno, 1943) and in rhesus monkeys the inferior cervical and first two thoracic ganglia (Sheehan and Pick, 1943). The function of the stellate ganglion in control of the heart, as it is revealed by animal experimentation with dogs, cats, and monkeys, does not agree entirely with that revealed by clinical observations. A partial explanation for this is provided by the fact that more thoracic ganglia are included in the stellate complex and a much greater bulk of the accelerator nerve arises from the ganglion in these animals than in man.

### Thoracic Portion of the Sympathetic System

The **thoracic portion** of the sympathetic trunk (Figs. 12-76; 12-77) contains a series of ganglia that correspond approximately to the thoracic spinal nerves, but the coalescence of adjacent ganglia commonly reduces the number to fewer than 12. The ganglia are oval, fusiform, triangular, or irregular in shape. They lie against the necks of the ribs in the upper thorax, gradually become more ventrally placed in the lower thorax, and finally lie at the sides of the bodies of the lowest thoracic vertebrae. The trunk is covered by the costal portion of the parietal pleura, and the interganglionic cords are between the pleura and the intercostal vessels, which they cross.

The roots of the ganglia are the white rami communicantes supplied by each spinal nerve to the corresponding ganglion or the trunk nearby. They contain predominantly small myelinated fibers (1 to 3  $\mu\text{m}$  in diameter), which leave the spinal cord through the ventral roots of the spinal nerves; the cell bodies are in the lateral column of gray matter in the spinal cord. Many of the preganglionic fibers fail to make synapses in their ganglia of entrance. From the upper five roots, these fibers take a cranial direction in the trunk, and for the most part, terminate in the cervical ganglia. Many of the fibers in the caudal six or seven rami traverse the trunk for a variable distance and then emerge into the splanchnic nerves, which are the roots of the celiac and related ganglia.

**FIG. 12-76.** The mediastinum from the right side. (Redrawn from Töndury.)

**Variations.** The first thoracic ganglion was independent of the stellate in 5 instances, and the second thoracic was independent in 22 out of 25 instances. Fusion occurred between the third and fourth three times; fourth and fifth five times; fifth and sixth once; sixth and seventh once; seventh and eighth four times; eighth and ninth twice; ninth and tenth twice (Pick and Sheehan, 1946). Small accessory ganglia occur at or near the junction of the communicating rami with the thoracic nerves, especially the upper four. Those at the white rami may provide sympathetic pathways to spinal nerves without traversing the sympathetic trunk (Ehrlich and Alexander, 1951).

The branches of the thoracic trunk are of three varieties: gray rami communicantes, visceral branches, and the splanchnic nerves.

**GRAY RAMI COMMUNICANTES.** The branches that form the gray rami communicantes are supplied to each spinal nerve. Usually two or three short branches are sent to each corresponding spinal nerve, and occasionally a slender branch reaches the next more caudal ganglion. When there are two or more branches to a single nerve, one branch may go to the anterior and one to the posterior primary division of the nerve. When the branches go only to the anterior primary division, the fibers turn back within the nerve to reach the posterior division (Dass, 1952). The gray rami are regularly proximal and transverse; the white rami, distal and oblique.

**VISCERAL BRANCHES.** Visceral branches are supplied to the cardiac, pulmonary, esophageal, and aortic plexuses.

**Cardiac Plexus.** Branches to the cardiac plexus from the first five thoracic ganglia vary in number both in different individuals and between the two sides in the same individual; there may be 15 or 20 in some cases. Larger ones usually come from ganglia; smaller ones, from intervening cords. They course medially close to the intercostal artery and vein, usually between the vessels and in the same connective tissue sheath, supplying filaments to them and communicating with the esophageal and pulmonary plexuses. From the right side they approach the deep part of the plexus, between the esophagus and the lateral aspect of the aorta. From the left side, they pass dorsal to the aorta and approach the deep part of the plexus from the right (Kuntz and Morehouse, 1930). Branches from the third, fourth, and fifth ganglia are more abundant than those from the first two; branches may

come from the sixth and seventh ganglia, but these usually enter the aortic network. The cross-sectional area of the thoracic cardiac nerves, as they enter the plexus, is twice as large as that of the cervical cardiac nerves (Saccomanno, 1943).

**Esophageal Branches.** Delicate esophageal branches from several of the thoracic ganglia, both upper and lower, may follow the intercostal vessels to the esophagus and join the plexus formed by the vagus, or filaments may be supplied by the cardiac and aortic plexuses, or by the splanchnic nerves.

**Posterior Pulmonary Plexus.** The posterior pulmonary plexus receives twigs from the second, third, and fourth ganglia that follow the intercostal arteries to the hilum of the lung.

**Aortic Network.** Branches to the aortic network come from the last five or six thoracic ganglia, from the cardiac plexus, and from the splanchnic nerves. Branches from these bundles accompany the branches of the artery, and probably supplement the splanchnic nerves.

**SPLANCHNIC NERVES.** The splanchnic nerves arise from the caudal six or seven thoracic and first lumbar ganglia. They are not, strictly speaking, true branches of the ganglia, since they contain only a small number of postganglionic fibers. They are composed principally of myelinated fibers, and accordingly have a whitish color and firm consistency similar to those of the somatic nerves. The small myelinated fibers (1 to 3  $\mu$ m in diameter), which predominate, are the preganglionic fibers that pass through the chain ganglia without synapses to become the roots of the celiac and related ganglia. Also present are large myelinated fibers, which are probably visceral afferents with their cell bodies in the dorsal root ganglia of the spinal nerves. Many of the fibers of all types probably come from spinal cord segments higher than the ganglia from which the branches arise.

**Greater Splanchnic Nerve.** The greater splanchnic nerve (Figs. 12-76; 12-77) is formed by contributions from the fifth (or sixth) to the ninth (or tenth) thoracic ganglia, which leave the ganglia in a medial direction and angle across the vertebral bodies obliquely in their caudalward course. They are combined into a single nerve that pierces the crus of the diaphragm and, after making an abrupt bend or loop ventralward, ends in the celiac ganglion by entering the lateral

border of its principal mass (Fig. 12-78). A small splanchnic ganglion occurs commonly in the nerve at the level of the eleventh or twelfth thoracic vertebra; it is considered part of the celiac ganglion formed by cells that failed to migrate as far as the large ganglion during embryonic development. Preganglionic fibers to the suprarenal glands are conveyed by the splanchnic nerves and pass through the celiac plexus without synapses in the ganglion.

**Lesser Splanchnic Nerve.** The lesser splanchnic nerve (Fig. 12-77) is formed by branches of the ninth and tenth thoracic ganglia or from the cord between them. It pierces the crus of the diaphragm with the greater splanchnic nerve and ends in the aorticorenal ganglion.

**Lowest Splanchnic Nerve.** The lowest splanchnic nerve (*least splanchnic nerve*), when present, is a branch of the last thoracic ganglion or of the lesser splanchnic nerve. It passes through the diaphragm with the sympathetic trunk and ends in the renal plexus.

**Variations.** The uppermost branch to the splanchnics in 25 dissections was the fourth ganglion once; fifth, twice; sixth, eleven times; seventh, seven times; eighth, four times (Pick and Sheehan, 1946). Filaments from the upper thoracic and stellate ganglia, from the cardiac nerves, or from the branches to the pulmonary and aortic plexuses sometimes continue downward to join the celiac plexus and have been considered a fourth splanchnic nerve. Lumbar splanchnic nerves are described below.

### Abdominal Portion of the Sympathetic System

The abdominal portion of the sympathetic trunk (Fig. 12-79) is situated ventral to the bodies of the lumbar vertebrae, along the medial margin of the psoas major. The cord connecting the last thoracic and first lumbar ganglia bends ventrally as it passes under the medial lumbocostal arch of the diaphragm, bringing the trunk rather abruptly into its ventral relationship with the lumbar vertebrae. The left trunk is partly concealed by the aorta; the right, by the inferior vena cava.

**LUMBAR GANGLIA.** The lumbar ganglia have no fixed pattern. The number varies from two to six, with four or five occurring in three-fourths of the trunks, but massive fusions are frequent and two specimens with four ganglia may bear no resemblance to

each other. Although the five individual lumbar ganglia should not be expected in any particular instance, each one occurs with sufficient frequency to make an anatomic description possible. The numbering of the ganglia is based upon the spinal nerves with which they are connected as well as upon the relationship to the vertebrae (Pick and Sheehan, 1946).

The **roots of the lumbar ganglia** (*white rami communicantes*) are found only as far as the second lumbar spinal nerve, the caudal limit of the thoracolumbar outflow. The preganglionic fibers for the rest of the lumbar and for the sacral and coccygeal ganglia run caudally in the trunk, mainly from these first two lumbar roots. One or two roots (*white rami*) are supplied to each of the first three lumbar ganglia (or their representatives in fused ganglia) by the spinal nerve one segment above; the roots take an oblique course caudalward while the branches to the spinal nerves (*gray rami*) take a transverse course (Botar, 1932). Thus the twelfth thoracic nerve sends roots to the first lumbar ganglion; the first lumbar nerve, to the second ganglion; and the second lumbar nerve, to the third ganglion.

The ganglia of the lumbar trunk, when independently represented, lie on the bodies of the corresponding vertebrae or the intervertebral discs caudally. The first ganglion is close to or partly concealed by the medial lumbocostal arch. The ganglion on the second lumbar vertebra is the most constant, largest, and most easily palpated and identified by the surgeon. The fifth ganglion is relatively inaccessible to the surgeon because of the common iliac vessels.

**Variations.** In 25 bodies, the first lumbar ganglion (identified by its rami) was independent in 13, fused with other ganglia in 10, and separated into two parts in 2; the second ganglion was missing in 2, independent in 12, fused in 7, and split in 4; the third ganglion was independent in 2, fused in 17, split in 4, and connected only with L 3 nerve in 3; the fourth ganglion was independent in one, fused in 12, split in 12, and of these 11 connected with L 4 only; the fifth ganglion was independent in 4, fused in 3, split in 18, and of these 15 connected with L 5 only (Pick and Sheehan, 1946).

The **branches of the lumbar trunk** may be divided into three groups: (1) the *gray rami communicantes*, (2) the lumbar splanchnic

**FIG. 12-78.** The lumbar portion of the right sympathetic trunk, the celiac ganglion, splanchnic nerves, suprarenal gland, and kidney. (Redrawn from Töndury.)

nerves, and (3) the visceral branches through the celiac plexus.

**GRAY RAMI COMMUNICANTES.** The branches that are the gray rami communicantes are supplied to each of the lumbar nerves. They take a transverse path, in contrast to the oblique path of the white rami, and they are more proximal than the white rami in the segments where both are present. They are longer than those in the thoracic region because the lumbar trunk is more ventrally

placed, at some distance from the spinal nerves, and they commonly accompany the lumbar arteries under the fibrous arches of the psoas, frequently splitting, doubling, and rejoining (Kuntz and Alexander, 1950).

**LUMBAR SPLANCHNIC NERVES.** The lumbar splanchnic nerves are two to four relatively short branches of the lumbar trunk at the level of the first, second, and third lumbar vertebrae, and are, therefore, caudal to the last root of the lesser splanchnic nerve. They

**FIG. 12-79.** The lumbar portion of the left sympathetic trunk, celiac and mesenteric ganglia, splanchnic nerves, hypogastric plexus, suprarenal gland, and kidney. (Redrawn from Töndury.)

pass either medialward, caudalward, and ventralward to join the aortic network, or, in the case of the most caudal lumbar splanchnic, caudalward and ventralward around the aorta to the inferior mesenteric ganglion or the hypogastric nerve. On the right side they pass between the aorta and the inferior vena cava (Trumble, 1934). Frequently they contain small groups of ganglion cells that are believed to be displaced from the sympathetic trunk (Harris, 1943).

**CELIAC GANGLION.** The celiac ganglion (semilunar ganglion) (Fig. 12-80) comprises two masses of ganglionic tissue approximately 2 cm in diameter, superficially resembling lymph nodes, which lie ventral and lateral to the abdominal aorta on each side at the level of the first lumbar vertebra. The ganglia are irregular in shape, are usually partly dispersed into several small ganglionic masses, and are connected with each other across the midline by a dense network

**Fig. 12-80.** View of the posterior abdominal wall, showing the celiac, aortic, and hypogastric plexuses of autonomic nerves. (Redrawn from Töndury.)

of bundles, especially caudal to the celiac artery. The ganglia lie on the ventral surface of the crura of the diaphragm, close to the medial border of the suprarenal glands. The right ganglion is covered by the inferior vena cava; the left is covered by the peritoneum of the lesser sac in close relation to the pancreas.

**AORTICORENAL AND SUPERIOR MESENTERIC GANGLIA.** The **aorticorenal** and **superior mesenteric ganglia** are masses that are more or less completely detached from the caudal portion of the celiac ganglion but represent portions of the larger celiac ganglionic complex. The aorticorenal ganglion lies at the origin of the renal artery; the superior mesenteric ganglion, at the origin of the corresponding artery. The **roots** of these ganglia

are the **splanchnic nerves** (discussed previously). Each greater splanchnic nerve enters the dorsal and lateral border of the main celiac ganglion (Fig. 12-80); the lesser splanchnic nerve enters the aorticorenal ganglion (Fig. 12-78), and the lowest splanchnic joins the renal plexus. They contain preganglionic fibers from the last six or seven thoracic spinal cord segments, which pass through the sympathetic trunk without synapses.

The **postganglionic fibers** that arise in the celiac ganglia form an extensive plexus (the celiac plexus) of nerve bundles and filaments, which branch off into subsidiary plexuses, in general following the branches of the abdominal aorta. The nerves from the celiac plexus pass down the aorta in the

form of a network that is penetrated by the inferior mesenteric artery. The more cranial lumbar splanchnic nerves make a stout contribution to this network and join the caudal lumbar splanchnic nerves to form thick ganglionated nerve bundles on each side of the midline. These bundles converge and meet at the bifurcation of the aorta, with a free decussation of fibers, and then continue as the **right and left hypogastric nerves**. Small ganglionic nodes are present, especially if the network is compressed (Trumble, 1934).

**INFERIOR MESENTERIC GANGLION.** The inferior mesenteric ganglion is more difficult to define in man than in many animals, but a considerable amount of ganglionic tissue is almost invariably present at the origin of the inferior mesenteric artery. The roots of the ganglion are provided by nerves from the celiac plexus, the celiac roots, and by the lumbar splanchnic nerves.

The inferior mesenteric ganglion in cats (Harris, 1943) is composed of three distinct masses arranged in a triangle about the origin of the inferior mesenteric artery. Ganglia are found in dogs, guinea pigs, rabbits, and monkeys also (Trumble, 1934).

**Branches.** The branches of the inferior mesenteric ganglion are (a) nerves that accompany the inferior mesenteric artery and its branches to supply the **colon**, and (b) fibers that join each **hypogastric nerve** and continue from the bifurcation to join the pelvic plexus. The hypogastric nerve crosses the medial side of the ureter and contributes to the ureteric network of nerves. It contains mainly fine unmyelinated fibers but has many medium myelinated fibers (4 to 6  $\mu\text{m}$ ) and a few large ones, probably afferent. The hypogastric nerves fan out into an extensive network just under the parietal peritoneum in the subserous fascia. They supply the rectal, vesical, prostatic, ureteric, and ductus deferens nerves (Ashley and Anson, 1946).

### Pelvic Portion of the Sympathetic System

The **pelvic portion** of the sympathetic trunk (Fig. 12-81) lies against the ventral surface of the sacrum, medial to the sacral foramina. It is the direct continuation of the lumbar trunk and contains four or five ganglia, smaller than those in other parts of the chain. Fusion of adjacent ganglia is common and cords connecting the trunks of the two sides across the midline occur regularly.

There are no white rami communicantes in the sacral region; small myelinated preganglionic fibers from the second, third, and fourth sacral nerves enter the pelvic plexus but they belong to the parasympathetic or craniosacral outflow rather than the sympathetic. The coccygeal ganglion is the most caudal ganglion of the sympathetic trunk; it is commonly a single ganglion, the **ganglion impar**, representing a fusion of the ganglia of the two sides, and usually lies in the midline but may be at one side.

The branches of the sacral and coccygeal ganglia which are the **gray rami communicantes** of the **sacral spinal nerves** are supplied to each of the sacral and the coccygeal nerves. In most instances, each ganglion, or its representative in a fused ganglion, supplies rami to two adjacent spinal nerves (Pick and Sheehan, 1946).

**Visceral branches** in variable numbers join the hypogastric and pelvic plexuses, and are supplied through them to the pelvic viscera and blood vessels (Trumble, 1934).

### Great Autonomic Plexuses

The two subdivisions of the autonomic nervous system, the sympathetic and parasympathetic, are combined into extensive plexuses in the thorax, abdomen, and pelvis, named respectively the cardiac plexus, the celiac plexus, and the pelvic plexus. Experimental and clinical observations have made it possible to trace the sympathetic and parasympathetic components to some extent, but on the morphologic evidence of dissections, it is almost impossible to distinguish the ultimate paths of the fibers belonging to the two systems. These plexuses also contain visceral afferent fibers, described in earlier pages.

### CARDIAC PLEXUS

The **cardiac plexus** (Fig. 7-19) is situated at the base of the heart, close to the arch of the aorta, and is traditionally subdivided into a superficial and a deep part for topographic reasons, although the functional associations do not justify this division. The sympathetic contribution is largely postganglionic; the parasympathetic, largely preganglionic, with scattered groups of ganglion cells.

**SUPERFICIAL PART.** The superficial part of the cardiac plexus (Fig. 12-77) lies in the arch

**Fig. 12-81.** Sagittal section of an adult female pelvis, with the peritoneum and subserous fascia partially dissected away to show the pelvic plexus of autonomic nerves. (Redrawn from Töndury.)

of the aorta somewhat on the left side between it and the bifurcation of the pulmonary artery. It is formed by the superior cervical cardiac branch of the left sympathetic and the lower of the two superior cardiac branches of the left vagus. A small ganglion, the cardiac ganglion (of Wrisberg<sup>1</sup>), is occasionally found in this plexus at the right side of the ligamentum arteriosum; it is probably a parasympathetic ganglion receiving pre-ganglionic fibers from the vagus.

The branches of the superficial cardiac plexus are as follows: (a) to the **deep cardiac plexus**, (b) to the **anterior coronary plexus**, and (c) to the **left anterior pulmonary plexus**.

**DEEP PART.** The deep part of the cardiac plexus is situated deep to the arch of the aorta, between it and the bifurcation of the trachea and cranial to the pulmonary artery.

<sup>1</sup>Heinrich August Wrisberg (1739-1808): A German anatomist (Göttingen)

It is much more extensive than the superficial part and receives all the cardiac branches of both vagi and sympathetic trunks, except the two mentioned previously which enter the superficial part (left superior sympathetic and left lower superior of the vagus). It also receives the lower cardiac branches of the vagus and the recurrent nerve, visceral rami from the upper cranial thoracic sympathetic ganglia, and communications from the superficial part of the cardiac plexus.

The branches of the deep part of the cardiac plexus may be divided into right and left halves.

The right half of the deep cardiac plexus gives branches that follow the right pulmonary artery. Those ventral to the artery are more numerous, and after contributing a few filaments to the anterior pulmonary plexus, continue into the anterior coronary plexus; those dorsal to the artery distribute a few fil-

aments to the right atrium and are then continued onward to form part of the posterior coronary plexus.

The left half of the deep cardiac plexus communicates with the superficial plexus, gives filaments to the left atrium and to the anterior pulmonary plexus, and is then continued into the greater part of the posterior coronary plexus.

The **posterior coronary plexus** (*left coronary plexus*) is larger than the anterior, and accompanies the left coronary artery. It is formed chiefly by filaments from the left half and by a few filaments from the right half of the deep plexus. It is distributed to the left atrium and ventricle.

The **anterior coronary plexus** (*right coronary plexus*) is formed partly from the superficial and partly from the deep parts of the cardiac plexus. It accompanies the right coronary artery and is distributed to the right atrium and ventricle (Stotler and McMahon, 1947).

#### CELIAC PLEXUS

The **celiac plexus** (*solar plexus*) (Figs. 12-78; 12-80) is situated at the level of the upper part of the first lumbar vertebra. It contains two large ganglionic masses and a dense network of fibers surrounding the roots of the celiac and superior mesenteric arteries. The denser part of the plexus lies between the suprarenal glands, on the ventral surface of the crura of the diaphragm and abdominal aorta, and dorsal to the stomach and the omental bursa, but it has extensive prolongations caudalward on the aorta and out along its branches. The celiac ganglia are described with the abdominal portion of the sympathetic system. The preganglionic parasympathetic fibers reach the plexus through the anterior (left) and posterior (right) vagi on the stomach. The preganglionic sympathetic fibers reach the celiac, aorticorenal, and superior mesenteric ganglia through the greater and lesser splanchnic nerves. These nerves also supply preganglionic fibers to the cells in the medulla of the suprarenal glands, which correspond developmentally to postganglionic neurons.

**SECONDARY PLEXUSES.** The secondary plexuses and prolongations from the celiac plexus follow.

The **phrenic plexus** (Fig. 12-80) accompa-

nies the inferior phrenic artery to the diaphragm. It arises from the superior part of the celiac plexus and is larger on the right side than on the left. It communicates with the phrenic nerve; at the point of junction with the right phrenic nerve, near the vena caval foramen in the diaphragm, there may be a small ganglion, the **phrenic ganglion**. The phrenic plexus gives filaments to the inferior vena cava, the inferior phrenic arteries, and the suprarenal and hepatic plexuses.

The **hepatic plexus** accompanies the hepatic artery, ramifying upon its branches and upon those of the portal vein in the substance of the liver. A large network accompanies the gastroduodenal artery and is continued as the inferior gastric plexus on the right gastroepiploic artery along the greater curvature of the stomach, communicating with the splenic plexus. Extensions from the hepatic plexus supply the pancreas and gallbladder, and there is a communication with the phrenic plexus.

The **splenic plexus**, containing mainly fibers from the left celiac ganglion and the anterior (left) vagus, accompanies the splenic artery to the spleen and in its course sends filaments along its branches, especially to the pancreas.

The **superior gastric plexus** (*gastric or coronary plexus*) accompanies the left gastric artery along the lesser curvature of the stomach and communicates with the anterior (left) vagus.

The **suprarenal plexus** (Fig. 12-78) is composed principally of short, rather stout, branches from the celiac ganglion, with some contributions from the greater splanchnic nerve and the phrenic plexus. The fibers that it contains are predominantly preganglionic sympathetics, which pass through the celiac ganglion without synapses and are distributed to the medulla of the suprarenal gland, where the cells are homologous with postganglionic neurons. Postganglionic fibers to the blood vessels are also present (Swinyard, 1937).

The **renal plexus** (Fig. 12-78) is formed by filaments from the celiac plexus, the aorticorenal ganglion, the aortic plexus, and the smallest splanchnic nerve. It accompanies the renal artery into the kidney, giving some filaments to the spermatic plexus and to the inferior vena cava on the right side (Christensen et al., 1951).

The **spermatic plexus** receives filaments

from the renal and aortic plexuses and accompanies the testicular artery to the testis. In the female, the ovarian plexus arises from the renal plexus, accompanies the ovarian artery, and is distributed to the ovary, uterine tubes, and the fundus of the uterus.

The **superior mesenteric plexus** is essentially the lower part of the celiac plexus; it may appear more or less detached from the rest of the plexus and frequently it contains a separate ganglionic mass, the superior mesenteric ganglion. Its vagus fibers come principally from the posterior vagus. It surrounds and accompanies the superior mesenteric artery, being distributed with the latter's pancreatic, intestinal, ileocolic, right colic, and middle colic branches, which supply the corresponding organs.

The **abdominal aortic plexus** (aortic plexus) (Fig. 12-80) is formed from both right and left celiac plexuses and ganglia and from the lumbar splanchnic nerves. It lies upon the ventral and lateral surfaces of the aorta between the origins of the superior and inferior mesenteric arteries. From this plexus arise the spermatic, inferior mesenteric, external iliac, and hypogastric plexuses, and filaments to the inferior vena cava.

The **inferior mesenteric plexus** surrounds the origin of the inferior mesenteric artery and contains a ganglion (Fig. 12-80), the inferior mesenteric ganglion, or thickened bundles that contain ganglion cells. It is derived from the aortic plexus, through whose celiac and lumbar splanchnic contributions it receives preganglionic as well as postganglionic fibers. It surrounds the inferior mesenteric artery, and divides into a number of subsidiary plexuses that accompany its branches—the left colic, sigmoid, and superior rectal—to the corresponding organs (Harris, 1943).

The **superior hypogastric plexus** (presacral nerve) (Fig. 12-80) is the caudalward continuation of the aortic and inferior mesenteric plexuses. It extends from the level of the fourth lumbar to the first sacral vertebrae and lies in the subserous fascia just under the peritoneum. It is at first ventral to the aorta, then lies between the common iliac arteries; crosses the left common iliac vein, and enters the pelvis to lie against the middle sacral vessels and the vertebrae. At the first sacral vertebra it divides into two parts, the right and left hypogastric nerves.

The **hypogastric nerve** may be a single

rather large nerve or several bundles forming a parallel network. It lies medial and dorsal to the common and internal iliac arteries, crosses the branches of the latter, and enters the inferior hypogastric plexus.

The **inferior hypogastric plexus** is a fanlike expansion from the hypogastric nerves at the proximal part of the rectum and bladder in the subserous fascia just above the sacrogenital fold. It receives filaments from the sacral portion of the sympathetic chain and from the deeper parts of the pelvic plexus.

## PELVIC PLEXUS

The **pelvic plexus** (Fig. 12-81) of the autonomic system is formed by the hypogastric plexus, by rami from the sacral portion of the sympathetic chain, and by the visceral branches of the second, third, and fourth sacral nerves. Through its secondary plexuses it is distributed to all the pelvic viscera.

**SECONDARY PLEXUSES.** The **middle rectal plexus** (*middle hemorrhoidal plexus*) is contained in the tissue of the sacrogenital fold and is therefore the most superficial part of the pelvic plexus with relation to the peritoneum. It is usually independent of the middle rectal artery, and except for its terminal filaments to the caudal sigmoid colon and rectum, it is several centimeters from the bowel itself. From its superficial position, it appears to be the continuation of the inferior hypogastric plexus, but the latter has a number of other continuations and the rectal plexus supplies the lower bowel with parasympathetic fibers through contributions from the visceral branches of the sacral nerves. It communicates with the superior rectal branches from the inferior mesenteric plexus (Ashley and Anson, 1946).

The **vesical plexus** arises from the anterior part of the pelvic plexus, its fibers derived from the superficial or hypogastric network and the deeper bundles from the sacral nerves. The filaments are divisible into periureteric, prostatic, seminal vesicle, and lateral vesical groups.

The **prostatic plexus**, from the deeper ventral part of the pelvic plexus, is composed of large nerves that are distributed to the prostate, seminal vesicles, and corpora cavernosa. The nerves supplying the corpora consist of two sets, the greater and lesser cavernous nerves, which arise from the ven-

tral part of the prostatic plexus, join with branches of the pudendal nerve, and pass beneath the pubic arch. Filaments at the base of the gland supply the prostatic and membranous urethra, the ejaculatory ducts, and the bulbourethral glands.

The **greater cavernous nerve** passes distalward along the dorsum of the penis, joins the dorsal nerve of the penis, and is distributed to the corpus cavernosum penis.

The **lesser cavernous nerves** perforate the fibrous covering of the penis near its root, and are distributed to the corpus spongiosum penis and the penile urethra.

The **vaginal plexus** arises from the caudal part of the pelvic plexus. It is distributed to the walls of the vagina and to the erectile tissue of the vestibule and clitoris.
